TECHNICAL REPORTS

No.	Page	No.	Page
1003. Correlation of Physical Properties with Molecular Structure for Some Dicyclic Hydrocarbons Having High Thermal-Energy Release Per Unit Volume. By P. H. Wise, K. T. Serijan, and I. A. Goodman, NACA.....	55	1020. Measurements of Average Heat-Transfer and Friction Coefficients for Subsonic Flow of Air in Smooth Tubes at High Surface and Fluid Temperatures. By Leroy V. Humble, Warren H. Lowdermilk, and Leland G. Desmon, NACA.....	343
1004. A Lift-Cancellation Technique in Linearized Supersonic-Wing Theory. By Harold Mirels, NACA.....	65	1021. Analysis of Plane-Plastic-Stress Problems With Axial Symmetry in Strain-Hardening Range. By M. H. Lee Wu, NACA.....	359
1005. Analytical Determination of Coupled Bending-Torsion Vibrations of Cantilever Beams by Means of Station Functions. By Alexander Mendelson and Selwyn Gendler, NACA.....	77	1022. Temperature Distribution in Internally Heated Walls of Heat Exchangers Composed of Non-circular Flow Passages. By E. R. G. Eckert and George M. Low, NACA.....	381
1006. Analysis of Thrust Augmentation of Turbojet Engines by Water Injection at Compressor Inlet Including Charts for Calculating Compression Processes with Water Injection. By E. Clinton Wilcox and Arthur M. Trout, NACA.....	97	1023. Diffusion of Chromium in Alpha Cobalt-Chromium Solid Solutions. By John W. Weeton, NACA.....	397
1007. Horizontal Tail Loads in Maneuvering Flight. By Henry A. Pearson, William A. McGowan, and James J. Donegan, NACA.....	117	1024. Calculation of the Lateral Control of Swept and Unswept Flexible Wings of Arbitrary Stiffness. By Franklin W. Diederich, NACA.....	413
1008. A Small-Deflection Theory for Curved Sandwich Plates. By Manuel Stein and J. Mayers, NACA.....	129	1025. Experimental and Theoretical Studies of Area Suction for the Control of the Laminar Boundary Layer on an NACA 64A010 Airfoil. By Albert L. Braslow, Dale L. Burrows, Neal Tetervin, and Fioravante Visconti, NACA.....	433
1009. Investigation of Fretting by Microscopic Observation. By Douglas Godfrey, NACA.....	135	1026. NACA Investigation of Fuel Performance in Piston-Type Engines. By Henry C. Barnett, NACA.....	453
1010. A Recurrence Matrix Solution for the Dynamic Response of Aircraft in Gusts. By John C. Houbolt, NACA.....	145	1027. Buckling of Thin-Walled Cylinder Under Axial Compression and Internal Pressure. By Hsu Lo, Harold Crate, and Edward B. Schwartz, NACA.....	647
1011. Dynamics of a Turbojet Engine Considered as a Quasi-Static System. By Edward W. Otto and Burt L. Taylor, III, NACA.....	177	1028. Effect of Aspect Ratio on the Air Forces and Moments of Harmonically Oscillating Thin Rectangular Wings in Supersonic Potential Flow. By Charles E. Watkins, NACA.....	657
1012. Investigation of the NACA 4-(5)(08)-03 and NACA 4-(10)(08)-03 Two-Blade Propellers at Forward Mach Numbers to 0.725 to Determine the Effects of Camber and Compressibility on Performance. By James B. Delano, NACA.....	189	1029. Compressive Strength of Flanges. By Elbridge Z. Stowell, NACA.....	675
1013. Effects of Wing Flexibility and Variable Air Lift Wing Bending Moments During Landing Impacts of a Small Seaplane. By Kenneth F. Merten and Edgar B. Beck, NACA.....	221	1030. Investigation of Separation of the Turbulent Boundary Layer. By G. B. Schubauer and P. S. Klebanoff, National Bureau of Standards....	689
1014. Study of Effects of Sweep on the Flutter of Cantilever Wings. By J. G. Barmby, H. J. Cunningham, and I. E. Garrick, NACA.....	229	1031. A study of the Use of Experimental Stability Derivatives in the Calculation of the Lateral Disturbed Motions of a Swept-Wing Airplane and Comparison With Flight Results. By John D. Bird and Byron M. Jaquet, NACA.....	709
1015. Analysis of Turbulent Free-Convection Boundary Layer on Flat Plate. By E. R. G. Eckert and Thomas W. Jackson, NACA.....	255	1032. A Comparison of Theory and Experiment for High-Speed Free-Molecule Flow. By Jackson R. Stalder, Glen Goodwin, and Marcus O. Creager, NACA.....	735
1016. Effect of Tunnel Configuration and Testing Technique on Cascade Performance. By John R. Erwin and James C. Emery, NACA.....	263	1033. Comparison Between Theory and Experiment for Wings at Supersonic Speeds. By Walter G. Vincenti, NACA.....	757
1017. Investigation of Frequency-Response Characteristics of Engine Speed for a Typical Turbine-Propeller Engine. By Burt L. Taylor, III, and Frank L. Oppenheimer, NACA.....	279	1034. Investigation of Spoiler Ailerons for Use as Speed Brakes or Glide-Path Controls on Two NACA 65 Series Wings Equipped With Full-Span Slotted Flaps. By Jack Fischel and James M. Watson, NACA.....	769
1018. A Theoretical Analysis of the Effect of Time Lag in an Automatic Stabilization System on the Lateral Oscillatory Stability of an Airplane. By Leonard Sternfield and Ordway B. Gates, Jr., NACA.....	291	1035. Analysis of Means of Improving the Uncontrolled Lateral Motions of Personal Airplanes. By Marion O. McKinney, Jr., NACA.....	795
1019. Relation Between Inflammables and Ignition Sources in Aircraft Environments. By Wilfred E. Scull, NACA.....	303		

No.	Page	No.	Page
1036. Experimental Investigation of the Effects of Viscosity on the Drag and Base Pressure of Bodies of Revolution at a Mach Number of 1.5. By Dean R. Chapman and Edward W. Perkins, NACA.....	805	1048. A Study of Effects of Viscosity on Flow Over Slender Inclined Bodies of Revolution. By H. Julian Allen and Edward W. Perkins, NACA....	1103
1037. General Method and Thermodynamic Tables for Computation of Equilibrium Composition and Temperature of Chemical Reactions. By Vearl N. Huff, Sanford Gordon, and Virginia E. Morrell, NACA.....	829	1049. Experimental Investigation of the Effect of Vertical-Tail Size and Length and of Fuselage Shape and Length on the Static Lateral Stability Characteristics of a Model With 45° Sweptback Wing and Tail Surfaces. By M. J. Queijo and Walter D. Wolhart, NACA.....	1117
1038. Wind-Tunnel Investigation of Air Inlet and Outlet Openings on a Streamline Body. By John V. Becker, NACA.....	887	1050. Formulas for the Supersonic Loading, Lift and Drag of Flat Swept-Back Wings With Leading Edges Behind the Mach Lines. By Doris Cohen, NACA.....	1146
1039. On the Particular Integrals of the Prandtl-Busemann Iteration Equations for the Flow of a Compressible Fluid. By Carl Kaplan, NACA....	909	1051. An Analysis of Base Pressure at Supersonic Velocities and Comparison With Experiment. By Dean R. Chapman, NACA.....	1187
1040. Spectra and Diffusion in a Round Turbulent Jet. By Stanley Corrsin and Mahinder S. Uberoi, Johns Hopkins University.....	915	1052. A Summary of Lateral-Stability Derivatives Calculated for Wing Plan Forms in Supersonic Flow. By Arthur L. Jones and Alberta Alksne, NACA.....	1211
1041. Equations and Charts for the Rapid Estimation of Hinge-Moment and Effectiveness Parameters for Trailing-Edge Controls Having Leading and Trailing Edges Swept Ahead of the Mach Lines. By Kenneth L. Goin, NACA.....	937	1053. Investigation of Turbulent Flow in a Two-Dimensional Channel. By John Laufer, California Institute of Technology.....	1247
1042. Some Effects of Nonlinear Variation in the Directional-Stability and Damping-in-Yawing Derivatives on the Lateral Stability of an Airplane. By Leonard Sternfield, NACA.....	1009	1054. Integrals and Integral Equations in Linearized Wing Theory. By Harvard Lomax, Max A. Heaslet, and Franklyn B. Fuller, NACA.....	1267
1043. A Numerical Method for the Stress Analysis of Stiffened-Shell Structures Under Nonuniform Temperature Distributions. By Richard R. Heldenfels, NACA.....	1019	1055. Comparison of Theoretical and Experimental Heat-Transfer Characteristics of Bodies of Revolution at Supersonic Speeds. By Richard Scherrer, NACA.....	1301
1044. The Method of Characteristics for the Determination of Supersonic Flow Over Bodies of Revolution at Small Angles of Attack. By Antonio Ferri, NACA.....	1039	1056. Theoretical Antisymmetric Span Loading for Wings of Arbitrary Plan Form at Subsonic Speeds. By John DeYoung, NACA.....	1317
1045. Supersonic Flow around Circular Cones at Angles of Attack. By Antonio Ferri, NACA.....	1055	1057. Analysis of the Effects of Boundary-Layer Control on the Take-Off and Power-Off Landing Performance Characteristics of a Liaison Type of Airplane. By Elmer A. Horton, Laurence K. Loftin, Jr., Stanley F. Racisz, and John H. Quinn, Jr., NACA.....	1353
1046. A General Integral Form of the Boundary-Layer Equation for Incompressible Flow With an Application to the Calculation of the Separation Point of Turbulent Boundary Layers. By Neal Tetervin and Chia Chiao Lin, NACA.....	1067	1058. Influence of Chemical Composition on Rupture Properties at 1200° F. of Forged Chromium-Cobalt-Nickel-Iron Base Alloys in Solution-Treated and Aged Condition. By E. E. Reynolds, J. W. Freeman, and A. E. White, NACA..	1385
1047. The Stability of the Compression Cover of Box Beams Stiffened by Posts. By Paul Seide and Paul F. Barrett, NACA.....	1087		

Letter of Transmittal

To the Congress of the United States:

In compliance with the provisions of the act of March 3, 1915, as amended, establishing the National Advisory Committee for Aeronautics, I transmit herewith the Thirty-seventh Annual Report of the Committee covering the fiscal year 1951.

HARRY S. TRUMAN.

THE WHITE HOUSE,
JANUARY 28, 1952.

Letter of Submittal

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS

WASHINGTON, D. C., *November 15, 1951.*

DEAR MR. PRESIDENT: In compliance with the act of Congress approved March 3, 1915, as amended (U. S. C. 1946, title 50, sec. 153), I have the honor to submit herewith the Thirty-seventh Annual Report of the National Advisory Committee for Aeronautics covering the fiscal year 1951.

The development of new types of aircraft slowed materially since the end of World War II but, since Korea, progress is now rapidly accelerating. The magnitude of the military effort required to check world-wide aggression makes it evident that America's aircraft must be superior in performance and military effectiveness to those of any other nation.

The Committee seeks, through timely and adequate research, to assure the success of the expanding aircraft program. The Committee believes that in order to support the military effort effectively, its scope of operations should be increased to the extent that availability of scientific manpower will permit.

Respectfully submitted.

JEROME C. HUNSAKER,
Chairman.

THE PRESIDENT,
The White House, Washington, D. C.

National Advisory Committee for Aeronautics

Headquarters, 1724 F Street NW., Washington 25, D. C.

Created by act of Congress approved March 3, 1915, for the supervision and direction of the scientific study of the problems of flight (U. S. Code, title 50, sec. 151). Its membership was increased from 12 to 15 by act approved March 2, 1929, and to 17 by act approved May 25, 1948. The members are appointed by the President, and serve as such without compensation.

JEROME C. HUNSAKER, Sc. D., Massachusetts Institute of Technology, *Chairman*

ALEXANDER WETMORE, Sc. D., Secretary, Smithsonian Institution, *Vice Chairman*

DETLEV W. BRONK, Ph. D., President, Johns Hopkins University.

JOHN H. CASSADY, Vice Admiral, United States Navy, Deputy Chief of Naval Operations.

EDWARD U. CONDON, Ph. D., Director, National Bureau of Standards.

HON. THOMAS W. S. DAVIS, Assistant Secretary of Commerce.

JAMES H. DOOLITTLE, Sc. D., Vice President, Shell Oil Co.

R. M. HAZEN, B. S., Director of Engineering, Allison Division, General Motors Corp.

WILLIAM LITTLEWOOD, M. E., Vice President, Engineering, American Airlines, Inc.

THEODORE C. LONNQUEST, Rear Admiral, United States Navy, Deputy and Assistant Chief of the Bureau of Aeronautics.

HON. DONALD W. NYROP, Chairman, Civil Aeronautics Board.

DONALD L. PUTT, Major General, United States Air Force, Acting Deputy Chief of Staff (Development).

ARTHUR E. RAYMOND, Sc. D., Vice President, Engineering, Douglas Aircraft Co., Inc.

FRANCIS W. REICHELDERFER, Sc. D., Chief, United States Weather Bureau.

GORDON P. SAVILLE, Major General, United States Air Force, Deputy Chief of Staff (Development).

HON. WALTER G. WHITMAN, Chairman, Research and Development Board, Department of Defense.

THEODORE P. WRIGHT, Sc. D., Vice President for Research, Cornell University.

HUGH L. DRYDEN, Ph. D., *Director*

JOHN F. VICTORY, LL. D., *Executive Secretary*

JOHN W. CROWLEY, JR., B. S., *Associate Director for Research*

E. H. CHAMBERLIN, *Executive Officer*

HENRY J. E. REID, D. ENG., Director, Langley Aeronautical Laboratory, Langley Field, Va.

SMITH J. DEFANCE, B. S., Director, Ames Aeronautical Laboratory, Moffett Field, Calif.

THIRTY-SEVENTH ANNUAL REPORT

OF THE

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS

WASHINGTON, D. C., *November 15, 1951.*

To the Congress of the United States:

In accordance with the act of Congress, approved March 3, 1915 (U. S. C. title 50, sec. 151), which established the National Advisory Committee for Aeronautics, the Committee submits its thirty-seventh annual report for the fiscal year 1951.

The United States is engaged in expanding military aviation to levels never before reached except in the midst of a major war. In Korea, our military aircraft are engaged in combat with airplanes of an unfriendly nation evidently able to build military aircraft of increasing capabilities. In this environment, the NACA is responsible for conducting an adequate program of scientific research to open the way for the design of aircraft and missiles of superior performance.

Since World War II the pace of technical development has increased. Until then, improvement in aircraft performance as a result of the application of scientific research proceeded at what now seems to be a relatively slow and orderly rate. Modest increases in speed, climb, range, or altitude were set as reasonable goals. Compressibility effects at high speeds were just beginning to be encountered and indicated a formidable barrier near the velocity of sound. This barrier has been found by research and experiment to be less formidable than supposed, and we now see the possibility of radical gains in airplane performance that are of great military significance. Such gains are also attainable by a potential enemy.

The increased complexity of modern high performance aircraft results in greatly increased costs, whether measured in manpower or dollars, and places more at stake in the success or failure of the research upon which superior performance is predicated. In view of the magnitude of the national effort to build up air power adequate to our national security, scientific research should proceed on a corresponding scale.

In the years immediately following World War II in appreciation of the probable significance to national security of applications of new knowledge of supersonic

aerodynamics and jet propulsion, the President and the Congress supported the NACA in an intensive program of fundamental scientific studies in these fields of aeronautical science. There was an urgent need to overcome a serious deficiency of basic information resulting from wartime concentration of research teams on immediate problems associated with the improvement of airplanes in service. Only by concentration on fundamentals may we expect to find leads to radically new developments which should pay off in the design of future aircraft. We do not know how long the present period of tension will last nor do we know what discoveries an enemy may make.

In addition, the Committee must not neglect less spectacular research to provide engineering information essential to the safety and economy of aircraft of all types, both civil and military. In this, the NACA has responsibility for the scientific study and practical solution of current problems, as crystallized in the discussions of our several subcommittees of experts. These subcommittees include designers, users, and research scientists. Research initiated to solve a current problem can be readily translated into practice. Such research, for example, makes possible an increase in thrust of current production engines and improved performance of the next lot of airplanes. The need for extended work in this area has been reflected in our budget estimates.

The military research and development program has been increased threefold, but to date the funds and manpower authorized for NACA have not expanded to support adequately the military effort. Therefore, the Committee urges an expansion in NACA effort to the extent that availability of scientific manpower will permit.

Presently, emphasis is on the military applications of research, but many of the results of NACA research effort are of value to civil aviation, as for example the work on ice prevention, fire prevention, effects of atmospheric turbulence, and work on aircraft stability and control. Much research for the improvement of

military aircraft is extended to obtain data needed by those responsible for the design, operation, or regulation of civil aircraft.

During the current year the Committee completed the installation of a transonic ventilated throat in the 16-foot wind tunnel at the Langley Aeronautical Laboratory. This installation is based on an invention by members of the NACA staff and is considered to be of exceptional importance because it permits model airplane tests at transonic air speeds in wind tunnels, hitherto impossible because of the choking of the conventional wind tunnel as the air speed approaches the velocity of sound.

In the formulation of its research programs, the Committee has been materially assisted by some 400

members of its 26 technical committees. These members include scientists from universities, engineers from industry, and experts from the civil and military agencies of the Government. The Committee continues to enjoy the loyal and effective support of its civil service staff in the execution of its policies and directives.

Parts I, II, and III of this annual report present a résumé of the unclassified scientific activities of the Committee, a description of the Committee's organization and membership, and the financial report for the fiscal year 1951.

Respectfully submitted.

JEROME C. HUNSAKER,
Chairman.

Part I—TECHNICAL ACTIVITIES

RESEARCH ORGANIZATION AND PROCEDURES

COMMITTEE LABORATORIES

Research of the National Advisory Committee for Aeronautics is conducted largely at its three laboratories—Langley Aeronautical Laboratory, Langley Field, Va.; Ames Aeronautical Laboratory, Moffett Field, Calif.; and Lewis Flight Propulsion Laboratory, Cleveland, Ohio. A subsidiary station is located at Wallops Island, Va., as a branch of the Langley Laboratory for conducting research on models in flight in the transonic and supersonic speed ranges. At Edwards, Calif., is located the NACA High-Speed Flight Research Station for research on transonic and supersonic airplanes in flight. The total number of employees, both technical and administrative, at these five stations and headquarters in Washington was 7,705 at the end of the fiscal year 1951.

TECHNICAL COMMITTEES AND RESEARCH COORDINATION

In carrying out its function of coordinating aeronautical research the Committee is assisted by a group of technical committees and subcommittees. The members of these committees are chosen for their particular knowledge in a specific field of aeronautics. They are selected from other Government agencies concerned with aviation including the Department of Defense, from the aircraft and air transport industries, and from scientific and educational institutions. These committees provide for the interchange of ideas and prevention of research duplication except where parallel efforts are desired. There are four technical committees under the National Advisory Committee for Aeronautics:

1. Committee on Aerodynamics.
2. Committee on Power Plants for Aircraft.
3. Committee on Aircraft Construction.
4. Committee on Operating Problems.

Each committee is supported by three to eight technical subcommittees.

In addition to the four technical committees, there is an Industry Consulting Committee established to assist the main Committee in formulation of general

policy. Membership of this Committee, as well as the technical committees and subcommittees, is listed in part II of this report.

Research coordination is further effected through discussions between Committee technical personnel and the research staffs of the aviation industry, educational and scientific organizations, and other aeronautical agencies. The Research Coordination Office is assisted by a west coast representative who maintains close contact with the aeronautical research and engineering staffs of that geographical area.

RESEARCH SPONSORED IN SCIENTIFIC AND RESEARCH INSTITUTIONS

For the 1951 fiscal year the NACA continued to make use of the unique research talents and facilities of universities and other nonprofit scientific institutions to find solutions for aeronautical problems. Both research proposals and the results from investigations have been carefully reviewed to maintain the quality of this part of the NACA program, and reports of the useful results of the sponsored research have been given the same wide distribution as other NACA reports.

The diversity of this sponsored research is indicated by the fact that 19 of the NACA technical subcommittees reviewed proposals for or the results of such investigations during the past year and that 48 reports of sponsored research were released. The technical aspects of the program are included with the descriptions of work under the various technical sections.

During the 1951 fiscal year the following institutions participated in the contract research program:

National Bureau of Standards, Forest Products Laboratory, Armour Research Foundation, Battelle Memorial Institute, Polytechnic Institute of Brooklyn, Brown University, California Institute of Technology, University of California, University of California at Los Angeles, Carnegie Institute of Technology, University of Cincinnati, Cornell University, University of Florida, Georgia Institute of Technology, Harvard University, Illinois Institute of Technology, University of Illinois, Iowa State College, Johns Hopkins University, Massachusetts Institute of Technology, University

of Michigan, Mount Washington Observatory, New York University, University of Notre Dame, Ohio State University, Pennsylvania State College, Princeton University, Purdue University, Stanford University, Stevens Institute of Technology, Syracuse University, Texas Agricultural and Mechanical College, University of Virginia, and University of Washington.

RESEARCH INFORMATION

Research results obtained in the Committee's laboratories and through research contracts are distributed in the form of Committee publications. Formal Reports, printed by the Government Printing Office, contain unclassified information and are available to the general public from the Superintendent of Documents. Technical Notes, released by the Committee in limited numbers, also contain unclassified research results of a more or less interim nature and are distributed to interested organizations throughout the country. Frequently, research results which will ultimately be published in Report form are issued initially as Technical Notes in the interest of speedy dissemination of data to American technical people and organizations. Translations of foreign material are issued in the form of Technical Memorandums.

In addition to unclassified publications the Committee prepares a large number of reports containing classified research information. For reasons of national security, these reports are controlled in their circulation. From time to time the classified reports are examined to determine whether it is in the national interest to declassify them. If it is found desirable to declassify the reports, they may be published as unclassified papers.

Another important means of transmitting quickly and efficiently the latest information in a particular field of research directly to designers and engineers working in that field is the holding of technical conferences from time to time at an appropriate NACA laboratory. Several conferences of this nature were held during the past year.

The Office of Aeronautical Intelligence was established in 1918 as an integral part of the Committee's

activities. Its functions are the collection and classification of technical knowledge on the subject of aeronautics, including the results of research and experimental work conducted in all parts of the world, and its dissemination to the Department of Defense, aircraft manufacturers, educational institutions, and other interested people. American and foreign reports obtained are analyzed, classified, and brought to the attention of the proper persons through the medium of public and confidential bulletins.

AERONAUTICAL INVENTIONS

By act of Congress, approved July 2, 1926 (U. S. C. title 10, sec. 310-r), an Aeronautical Patents and Design Board was established consisting of the Assistant Secretaries for Air of the Departments of War, Navy, and Commerce. In accordance with that act as amended by an act, approved March 3, 1927, the National Advisory Committee for Aeronautics is charged with the function of analyzing and reporting upon the technical merits of aeronautical inventions and designs submitted to any agency of the Government. The Aeronautical Patents and Design Board is authorized, upon the favorable recommendation of the Committee to "determine whether the use of the design by the Government is desirable or necessary and evaluate the design and fix its worth to the United States in an amount not to exceed \$75,000."

Recognizing its obligation to the public in this respect the Committee has continued to accord to all correspondence on such matters full consideration. All proposals received have been carefully analyzed and evaluated and the submitters have been advised concerning the probable merits of their suggestions. Many personal interviews have been granted inventors who visited the Committee's offices, and technical information has been supplied when requested.

* * * * *

The following detailed summary of unclassified research, completed during the fiscal year 1951, is organized to reflect the areas of research over which each technical committee and related subcommittee has cognizance.

AERODYNAMIC RESEARCH

During the past year there has been an increase in research directed specifically at the problems of high-speed airplanes and guided missiles. Aerodynamic research to permit efficient operation of airplanes at transonic speeds has continued to receive special emphasis, and information has been obtained in this speed range from flights of special research airplanes, rocket-powered free-flight models, freely-falling bodies, and

from very small models on wind-tunnel bumps or by the wing-flow method in flight. There has, however, been a serious need for techniques to permit detailed systematic large-scale experiments to be made in wind tunnels through the speed of sound. As a result of extensive research on wind-tunnel design, suitable techniques have been developed, and the Langley 8-foot and 16-foot wind tunnels were modified to permit testing

through the speed of sound. These modified tunnels are contributing to a better understanding of aerodynamic problems in the transonic speed range.

Theoretical and experimental research on high-speed airplane design problems has been directed generally at the establishment of technical information to permit the selection of the most efficient configurations for flights at transonic and supersonic speeds which will also have satisfactory flying characteristics at low speeds for landing and take-off. As the high-speed requirements increased, the landing requirements have become more difficult to meet and it has been necessary to continue research at low speeds on these problems.

In addition to studies of performance problems of guided missiles, considerable attention has been directed during the past year to the problems of stability and control. In this field particular emphasis has been placed on the cross-coupling effects experienced by various missile configurations and on automatic control problems.

The NACA is assisted in guiding the aerodynamic research activities of its laboratories by the Committee on Aerodynamics and its eight technical subcommittees. Results of the research which are most pertinent to the design and development of military airplanes and guided missiles are summarized and presented at technical conferences held during the year with the representatives of the military services and their contractors, in order to assist designers in making early application of these results.

In the sections which follow a description is given of some of the Committee's recent unclassified work in aerodynamics.

FLUID MECHANICS

Investigation of Airfoils at Low Speeds

Low-speed investigations of two-dimensional airfoils have been devoted to a large extent to the study of flow phenomena at high lifts and the development of methods for the improvement of high lift characteristics. Reported in Technical Note 2235 is an investigation of the boundary-layer and stalling characteristics of the NACA 64A-010 airfoil section in the Ames 7- by 10-foot wind tunnels. The results show the small region of separated flow or "bubble" near the leading edge, characteristic of airfoils with small leading-edge radii. At an angle of attack of 9.5° the separated flow failed to reattach to the surface, causing the stall. Since there was no turbulent separation at the trailing edge, the lift-curve peak was sharp and the stall occurred suddenly and with no warning.

An investigation was also conducted in the Ames 7- by 10-foot wind tunnels to determine the possibility of

delaying the flow separation that occurs near the leading edge of the NACA 63₁-012 airfoil section and of improving its stalling characteristics by modifications of the contour near the leading edge. This study is reported in Technical Note 2228. The greatest improvement was obtained with modifications that incorporated an increase in camber and modifications to the leading-edge shape were more effective than drooped-nose flaps.

The results of a comprehensive investigation of the stalling characteristics of airfoil sections at low subsonic speeds in the Ames 7- by 10-foot wind tunnels have been summarized in Technical Note 2502. Several types of stall encountered with airfoils ranging in thickness from that for a slow, light airplane to that for a possible supersonic application are described in detail in conjunction with the characteristic flows in the boundary layer.

The increases in airplane lift-drag ratio associated with increasing aspect ratio are limited by the high profile-drag coefficients associated with the thick wing-root sections which are structurally necessary on wings of high aspect ratio. An investigation has therefore been made of NACA 64-series airfoils of 32- and 40-percent-chord thickness in the Langley low-turbulence tunnels to determine whether the high profile-drag coefficients of thick airfoils can be reduced by boundary-layer control through a single suction slot. The results obtained for the 32- and 40-percent-thick sections together with other available airfoil section data were used to calculate the characteristics of a number of hypothetical wings. These calculations indicate that the maximum attainable lift-drag ratio of structurally feasible wings and of the corresponding airplanes may be increased appreciably by the use of such thick wings with boundary-layer control. The results are presented in Technical Note 2405.

It has been found that in the higher ranges of landing speeds compressibility effects on maximum lift can become appreciable. As part of a program to explore this phenomenon, the effects of Mach number and Reynolds number on the maximum lift coefficient of a wing of NACA 66-series airfoil sections were determined in the Langley 19-foot pressure tunnel and are published in Technical Note 2251. The ranges of Mach number and Reynolds number extended up to 0.34 and 8.0 million, respectively. It was found that for a given value of Mach number, the values of maximum lift coefficient were increased when the Reynolds number was increased. For a given value of Reynolds number, an increase in Mach number at first caused only small reductions in maximum lift coefficient, but the reduction was large after the critical speed was exceeded.

Theoretical Investigations of Two-Dimensional Compressible Flows

Theoretical investigations of two-dimensional compressible flows are being continued with particular reference to the difficult transonic speed range. At the Langley Laboratory the Prandtl-Busemann small-perturbation method has been utilized to obtain the flow of a compressible fluid past a wave-shaped, infinitely long wall. When the essential assumption for transonic flow is introduced—that all Mach numbers in the region of flow are nearly unity—the expression for the velocity potential takes the form of a power series in the transonic similarity parameter. On the basis of this form of the solution, an attempt has been made to solve the nonlinear differential equation for transonic flow past a wavy wall. The results of this analysis exhibit clearly the inherent difficulties encountered in nonlinear flow problems. Nevertheless, the investigation has been carried in a rigorous manner to the point where the question of the existence or nonexistence of a mixed potential flow free of discontinuities can be settled by the behavior of a single power series in the transonic similarity parameter. The calculation of the coefficients of this dominant power series has been reduced to a routine computing problem by means of recursion formulas resulting from the solution of the differential equation and the boundary condition at the wall. One of the results of the analysis is the rigorous statement of a limit of applicability of the transonic similarity concept. The results are presented in TN 2383.

In Technical Note 2253 it is shown that it is possible to solve the Prandtl-Busemann iteration equations by means of the familiar concepts of a distribution of sources and sinks. The method is limited to the treatment of thin, sharp-nose, symmetric, two-dimensional profiles. An explicit expression is derived for the second-order velocity potential and velocity components, and a method for obtaining higher-order terms is indicated. The velocity at the surface of the Kaplan bump is evaluated to illustrate the method.

The relaxation method has been proposed as a means of calculating pressure distributions on two-dimensional bodies at high speeds, and a comparison is shown in Technical Note 2174 between the experimental pressure distribution for an NACA 0012 profile and the theoretical pressure distribution obtained by this method. The comparison showed good agreement at low speeds, but at higher Mach numbers the theoretical calculations indicated higher negative pressure coefficients than were obtained experimentally.

An integral method of calculating two-dimensional compressible flows past thin airfoils, with particular reference to the transonic speed range is presented in

Technical Note 2130. By an appropriate choice of streamline curvature, this method permits the flow pattern about a thin airfoil to be calculated in a comparatively simple manner. The results presented include velocity distributions for various symmetric sections. Comparison with other theories and with available experimental data indicate at least qualitatively good agreement.

The transonic similarity law for two-dimensional flow, derived by von Karman, has been investigated by an iteration procedure and is presented in Technical Note 2191. The boundary condition of zero velocity normal to the body was satisfied at the body rather than near the body, as was done by von Karman. The results showed that the velocity potential can be expressed in terms of a similarity parameter and were in agreement with those of von Karman.

Theoretical investigations of two-dimensional compressible flows by several educational institutions under contract to the NACA are being continued. At the New York University an approximate method of solving the nonlinear differential equation for two-dimensional subsonic compressible flow by means of the variational method is being used. The general problem of steady irrotational flow past an arbitrary body is formulated and two examples have been carried out, namely, the flow past a circular cylinder and the flow past a thin curved surface. The variational method yields results of velocity and pressure distributions which compare well with those found by other methods.

The problem of two-dimensional flow behind a curved stationary shock wave has been considered analytically at the Massachusetts Institute of Technology. The method, which is presented in Technical Note 2364, assumes a given shock-wave shape, which automatically determines certain initial conditions on the flow variables; and the flow pattern, including any body shape, follows from the initial conditions. Approximate analytic expressions are found for the stream function in the subsonic region following the shock and, after the stream function is obtained, the flow density is determined by Bernoulli's equation, which connects the density with the derivatives of the stream function. The final solution can then be determined from the velocity field thus obtained.

Technical Note 2356 presents the results of a study, made at Cornell University, of the two-dimensional transonic flow past airfoils. The problem of constructing solutions for transonic flow over symmetric airfoils is treated and simplification of the mapping of the incompressible flow is emphasized. In the case of a symmetric Joukowski airfoil without circulation, the mapping is relatively simple, but the coefficients in the power series are difficult to evaluate. As a means of

simplification, an approximate flow is used which differs only slightly from the exact incompressible one when the thickness is small. Flow with circulation is also considered by the same method.

At the Johns Hopkins University an investigation has been made of the transient behavior of an airfoil in supersonic flow due to pitching, flapping, and vertical gusts by means of the Fourier integral method. By using a convolution integral, the aerodynamic effect of any arbitrary motion of the airfoil can be determined, if the aerodynamic response of the airfoil to a step-function disturbance is known. As useful examples, the harmonically oscillating airfoil with different modes or degrees of freedom is analyzed for the complete time history, for the case in which the motion starts abruptly from rest. In carrying out the investigation, a new integral has been introduced which is believed to play an equivalent part in supersonic flutter to the Theodorsen function in the flutter problems of incompressible flow. The results are presented in Technical Note 2333.

Investigation of Wings and Bodies at Transonic and Supersonic Speeds

An essential part of the correlation of aerodynamic data is a knowledge of the correspondence between the flow fields about similar bodies at related speed conditions. An investigation was made, therefore, at the Ames Laboratory which extended similarity laws for transonic flow to include finite-span wings. Under the assumptions of transonic small-perturbation potential theory, it was shown that similitude in pressure, lift, pitching moment, and pressure-drag coefficients depend upon the constancy of two parameters. The application of these results led to an essential improvement in the manner of relating experimental wing characteristics at near-sonic speeds. This work has been reported in Technical Note 2273.

Source distribution methods for evaluating the aerodynamics of thin finite wings at supersonic speeds are summarized and extended in Report 951. The fundamental equations were derived in general form for both time-independent and time-dependent wing motions and were applied to solve a large variety of aerodynamic problems. In Technical Note 2303 a method was developed for relating the solution of a wing to the known solution of a simpler wing. This method permits complicated flow fields to be solved in a straightforward manner.

At the Johns Hopkins University, von Karman's Fourier integral method in supersonic wing theory, derived directly from the basic concepts of the harmonic source and doublet, has been applied to investigate the general solution of the wave drag of a tapered swept wing with a symmetrical diamond airfoil profile, cover-

ing various geometrical arrangements of the planform. The theory has also been applied to find the downwash distribution in the plane of the wing on which the pressure distribution is preassigned. A number of examples are given. This work has been done under contract to the NACA and the results are presented in Technical Note 2317.

The flow around cones without axial symmetry and moving at supersonic velocity has been analyzed and the results of this analysis are presented in Technical Note 2236. Singular points were shown to exist in the flow around the cone if no axial symmetry exists. The concept of a vortical layer around the cone at small angles of attack was introduced, and the correct values of the first-order terms of the velocity components were determined. It was shown that good agreement with experimental results can be obtained if the complete equation for the pressure distribution is used.

The transonic similarity law, as applied to bodies of revolution, has been investigated and the results presented in Technical Note 2239. The results obtained were in approximate agreement with those of von Karman in the region of the flow field not too close to the body. In the neighborhood of the body a different similarity law was obtained. In another investigation the integral method used to obtain compressible flow past two-dimensional shapes (Technical Note 2130) was applied to the calculation of the compressible flow past slender bodies of revolution. Good agreement of the resulting velocities on ellipsoids of revolution with those obtained by other methods was found. The investigation is reported in Technical Note 2245.

The pressure acting on the base of a body of revolution flying at supersonic velocity is of considerable importance because the base drag can, in some cases, represent more than half of the total drag. It is essential that the factors contributing to this drag be explored to enable a reasonable drag prediction to be made in the design of missiles and to provide information from which possible base-drag reductions may be realized. One such factor is the presence of tail surfaces near the base of the body. Since the pressures in the vicinity of the trailing edge of the tail surfaces at zero angle of attack are normally less than the free-stream values, the interaction of these pressures with the flow behind the base may produce a reduction in the base pressure and, hence, an increase in the base drag. Accordingly, experimental measurements of the base pressure on an unboattailed body of revolution in combination with rectangular tail surfaces were made at the Ames Laboratory to investigate the effects of tail surfaces on base drag. The results of the investigation showed that the addition of tail surfaces with the trailing edge near the base of the body incurred a significant increase in base

drag. For example, the increase was about 70 percent at a Mach number of 1.5 for a cruciform tail having a 10-percent-thick biconvex airfoil section. The base-drag penalty due to tail surfaces was found to increase with an increase in the airfoil thickness ratio and with the number of tail surfaces and to decrease with an increase in Mach number. It was also found that this base-drag increment could be essentially eliminated by moving the tail so that the trailing edge was about one chord-length ahead of or behind the base of the body. The results are presented in Technical Note 2360.

Research in the Hypersonic Speed Range

In the Thirty-sixth Annual Report several facilities and techniques permitting supersonic research to be extended into the hypersonic speed range were described. During the past year this work has been continued and, in addition, progress has been made in extending theoretical calculations into the hypersonic range.

The accuracy of Tsien's hypersonic similarity rule, and the range of Mach numbers and fineness ratios over which it can be applied, have been investigated theoretically. A first investigation, which ignored rotation effects, showed that the rule applied with good accuracy over a range from moderate supersonic speeds up to hypersonic speeds for a wide range of body fineness ratios. This work has been reported in Technical Note 2250. An investigation of the effects of rotation, presented in Technical Note 2399, showed that the omission of these effects in the previous investigation did not have a significant effect on accuracy within the expected range of validity of hypersonic similarity.

An analysis has been performed to determine the lift and drag characteristics of conical bodies, flat plates, cylinders and spheres in a free-molecule flow field. The calculations were made for a range of Mach numbers from 0 to 24. It was found that the aerodynamic coefficients approached constant values at the very high speeds. It was also found that the lift-drag ratio for bodies in a free-molecule flow field are extremely low. The results are reported in Technical Note 2423.

Theoretical investigations have also been made to determine the similarity law for hypersonic flow about slender three-dimensional shapes in terms of customary aerodynamic parameters. A first investigation, which considered only steady flows, employed the law to determine relation for correlating the pressures acting on, and the aerodynamic coefficients of, related bodies and results are reported in Technical Note 2443. In the special case of inclined bodies of revolution, the expressions for the aerodynamic coefficients were extended to include some significant effects of the viscous cross force.

A theoretical analysis which determines the airfoil profile having minimum pressure drag for a given

structural requirement was reported in Technical Note 2264. The general method was developed and applied to linearized flow theory. The principal results of the investigation were that the optimum airfoil at hypersonic velocities has a trailing-edge thickness slightly less than the maximum airfoil thickness and the optimum airfoil at supersonic velocities generally has a moderately thick trailing edge. Curves were developed which enable optimum airfoil profiles to be determined rapidly for a given Mach number, base pressure, and structural requirement.

Condensation of the components of air has been found to occur in hypersonic wind tunnels. Because of the rapid expansion and cooling of the air in the nozzles of these tunnels, the temperature of the air drops below the liquefaction point. In order to study this condensation process, the Langley Laboratory has made an investigation of optical methods for measuring size and concentration of condensation particles, and it has been found that the polarization and angular distribution of light scattered by condensation particles can be used to measure these quantities. The results of this investigation are presented in Technical Note 2441.

Boundary-Layer Research

The existence of localized regions of laminar-boundary-layer separation on airfoils both behind the position of minimum pressure at the ideal angle of attack and near the leading edge at high angles of attack has been recognized, but the parameters controlling such regions have not been fully understood. Consequently, an experimental investigation was made at the Langley Laboratory to study the localized region of laminar separation behind the point of minimum pressure on an NACA 66₃-018 airfoil section at zero angle of attack and at several Reynolds numbers. The results, presented in Technical Note 2338, confirmed the idea that such separation regions are characterized by a length of laminar boundary layer followed by transition and subsequent reattachment as a turbulent boundary layer and established some of the quantitative characteristics of the phenomenon.

At the Lewis Laboratory an analysis has been made of the stability of the laminar boundary layer between parallel streams of an incompressible fluid. Calculations based on this analysis showed that the flow instability occurs at much lower Reynolds number for the free boundary layer between streams than for the boundary layer on a flat plate with no pressure gradient. The results of this study are presented in Report 979.

An investigation of methods for treating the three-dimensional compressible laminar boundary layer is reported in Technical Note 2279. The equations of mo-

tion are shown therein to be simplified by the introduction of a two-component vector potential and by the use of a transformation which converts the equations into nearly incompressible form. Several examples, including the flow over flat plates with arbitrary leading-edge contours, are discussed.

Numerical solutions of quantities appearing in the von Karman momentum equation for the development of a turbulent boundary layer in plane and in radial compressible flows along thermally insulated surfaces are presented in Technical Note 2337 for a range of Mach number from 0.1 to 10. Through the use of these tables, approximate calculation of boundary-layer growth is reduced to routine arithmetic computation.

Experimental data, from several sources, for skin friction of turbulent boundary layers under adverse pressure gradients are analyzed in Technical Note 2431. Data obtained by momentum-balance methods were compared with data obtained by hot-wire and heat-transfer methods. A new integral energy parameter was introduced and its relation to skin-friction data was demonstrated on the basis of available material.

At the Ames Laboratory an analysis has been made to determine the skin-friction and heat-transfer characteristics of the turbulent boundary layer on a flat plate at supersonic speeds. A review of existing analyses has also been made and a test performed in the Ames heat transfer tunnel to measure the skin friction in the turbulent boundary layer of a flat plate at a Mach number of 2.4. It was found that the analysis which most closely corresponded to the experimental results was an extended version of the Frankl-Voishel analysis, which has been reported in Technical Memorandum 1053. The test data and analysis have been reported in Technical Note 2305.

A series of heat-transfer investigations were conducted on bodies of revolution with laminar boundary layers at Mach numbers from 1.49 to 2.13. In addition, a comparison between theory and experiment has been made for a body of revolution with a laminar boundary layer and a nonuniform surface temperature. The theoretical and experimental heat-transfer results are in good agreement for both heated and cooled bodies with both uniform and nonuniform surface temperatures. The qualitative effects of heat transfer on transition were found to be in agreement with the implications of Lees' boundary-layer-stability theory.

Detailed measurements of shock-wave boundary-layer interaction which have been made in wind tunnels have been limited to small or moderate Reynolds numbers, and previous flight tests at high Reynolds numbers have been limited to pressure measurements. Therefore, tests were made on an airplane wing in flight to

investigate the region of shock-wave interaction with a thick turbulent boundary layer at full-scale flight Reynolds numbers, utilizing both a schlieren apparatus and pressure measurements. Good correlation with theoretical and wind-tunnel investigations of boundary-layer shock-wave interaction was obtained, particularly with respect to the lower Mach numbers at which a forked or bifurcated type of shock wave appeared. The boundary layer did not appear to thicken behind the normal shock wave. Considerable thickening, associated with separation, did occur, however, with increasing Mach number after the formation of the forked shock wave. The density gradient in the boundary layer appeared to increase markedly just behind the shock wave. This stronger gradient, however, appeared to be dissipating at approximately five to six boundary-layer thicknesses behind the shock.

At the Lewis Laboratory supersonic flow against blunt bodies placed in boundary layers or wakes has been investigated and is discussed in Technical Note 2418. It was concluded that wedge-shaped or conical dead-air regions should form ahead of the body if part of the upstream velocity profile is subsonic and if the body is fairly thick relative to the initial boundary layer or wake thickness. A quantitative theoretical analysis of this type of flow was made and the results were compared with experiment.

In a contract investigation carried out at the California Institute of Technology, measurements have been made at Mach numbers from about 1.3 to 1.5 of reflection characteristics and the relative upstream influence of shock waves impinging on a flat surface with both laminar and turbulent boundary layers. The difference between impulse and step waves is discussed and their interaction with the boundary layer were compared in Technical Note 2334. General considerations on the experimental production of shock waves from wedges and cones and examples of reflection of shock waves from these bodies were presented, as were also some examples of reflection of shock waves from supersonic shear layers.

At the National Bureau of Standards an investigation sponsored by the NACA was conducted on a turbulent boundary layer near a smooth surface with pressure gradients sufficient to cause flow separation. The Reynolds number was high, but speeds were entirely within the incompressible flow range. The investigation consisted of measurements of mean flow, three components of turbulence intensity, turbulent shearing stress, and correlations between two fluctuation components at a point between the same component at different points. Results are given in Technical Note 2133 in the form of tables and graphs. The discussion deals

first with separation and then with the more fundamental question of basic concepts of turbulent flow.

Aerodynamic Heating and Heat Transfer

As was pointed out in the Thirty-sixth Annual Report, knowledge of aerodynamic heating and heat transfer phenomena has become of increasing importance as airplane and missile flight speeds have increased into the supersonic region, and during the past year considerable effort has been directed toward the understanding of these phenomena.

Tests have been conducted at the Ames Laboratory to determine the effect of surface heating on the transition Reynolds numbers on a flat plate at a Mach number of 2.4. It was found that surface heating had a strong effect in lowering the minimum Reynolds number for transition. Measured skin-friction coefficients for the laminar portion of the boundary layer were in excellent agreement with other investigations and were 35 percent higher than the values predicted theoretically by Crocco. The data have been reported in Technical Note 2351.

Most aircraft or missiles will not have a constant surface temperature. Consequently, it is necessary to determine the effect of a variable surface temperature on the local heat-transfer rate in order to design skin-cooling systems. An analysis has been made which shows the effect of a variable stream-wise surface temperature on local heat-transfer rates. An interesting side light arising from the investigation shows that the use of plug-type heat meters, in which a small segment of the aircraft skin is heated or cooled to a different temperature than the surrounding skin, may introduce large errors in the determination of the local heat-transfer coefficients. This analysis has been published as Technical Note 2345.

An analytical method is presented in Technical Note 2296 for obtaining turbulent temperature recovery factors for a thermally insulated surface in supersonic flow. The analysis, conducted at the Lewis Laboratory, indicated that the recovery factor decreased with increasing Mach number. For the range of Prandtl number considered (0.65 to 0.75), the recovery factors at a stream Mach number of 10 were, on the average, about 5 percent lower than the limiting values at zero Mach number.

A comparison has been made of free-molecule-flow theory with experimental measurements of drag and temperature-rise characteristics of a transverse circular cylinder. The measured values of the cylinder center-point temperature confirmed the salient point of the heat-transfer analysis, which was the prediction that an insulated cylinder would attain a temperature higher than the stagnation temperature of the stream. Good

agreement was obtained between the theoretical and experimental values for the drag coefficient. The data have been reported in Technical Note 2244.

Experiments have been made at the Ames Laboratory to determine the heat-transfer characteristics of cylinders over a wide range of densities encompassing the free-molecule, slip and continuum flow regimes, and the results are presented in Technical Note 2438. Good correlation of the data was obtained over a range of Reynolds numbers from 0.02 to 100 and a range of Mach numbers from 1.9 to 3.2. The Knudsen number (ratio of mean free molecular path to cylinder diameter) varied from 0.02 to 10. Several important conclusions were drawn from the results of this investigation: It was found that fully developed free-molecule flow occurred when the Knudsen number was 2 or greater. For Knudsen numbers greater than 0.2, the temperature recovery factor exceeded unity even though free-molecular flow was not fully developed.

In an investigation at the Lewis Laboratory, analyses were made for fully developed laminar and turbulent flow in smooth circular tubes of fluids having a Prandtl number of 1.0. The analyses took into consideration the variation of fluid properties. Velocity and temperature profiles, together with local heat-transfer and friction coefficients, were predicted. In order to check the analysis for turbulent flow, velocity and temperature profiles and corresponding local heat-transfer and friction coefficients were also experimentally determined for air in smooth tubes at high heat-transfer rates. The analytical and experimental results were found to be in good agreement. Both indicated that for the turbulent flow of gases the radial velocity and temperature profiles tended to become more uniform as the surface-to-fluid temperature ratio increased. At constant Reynolds number, the local heat-transfer and friction coefficients decreased with an increase in surface-to-fluid temperature ratio. The effects of temperature ratio could be eliminated when the fluid properties, including density in the Reynolds number, were evaluated at a temperature close to the average of the fluid and surface temperatures. The results of these analyses are presented in Technical Notes 2242 and 2410.

Average heat-transfer and friction coefficients have also been measured for the turbulent flow of air in smooth tubes. This investigation covered an over-all range of Reynolds numbers up to 500,000, tube exit Mach numbers up to 1.0, inlet-air temperatures from 535° to 3050° R., average surface temperatures from 535° to 1500° R., length-diameter ratios from 30 to 120, and heat fluxes to 150,000 BTU per hour per square foot. Three tube entrance configurations were studied. Most of the data are for heat addition to the air; some results are for heat extraction from the air. Data have

also been obtained for tubes of noncircular cross section. An effect of surface-to-fluid temperature ratio was found to exist when the average coefficients were correlated with other pertinent variables by conventional methods. The effect was eliminated in the same manner as for the local coefficients. Correlation equations for heat transfer and friction were obtained which adequately represent all the experimental data for smooth tubes.

An analytical investigation of the compressible flow processes occurring in the passages of high heat-flux exchangers is continuing at the Lewis Laboratory. Charts are presented in Technical Notes 2186 and 2328 for convenient determination of the compressible-flow pressure drop sustained by monatomic and diatomic gases (assuming constant heat capacities during the process) flowing at high subsonic speeds in constant-area passages under the simultaneous influence of friction and heat addition.

STABILITY AND CONTROL

Static Stability Investigations

The use of end plates has been suggested as a possible means of relieving some of the adverse lateral stability and control problems experienced with swept wings. An investigation was therefore conducted in the Langley 300-mph 7- by 10-foot tunnel to determine the effects of end plates of various sizes and shapes on the stability and control characteristics of several swept wings. The results of this investigation, presented in Technical Note 2229, indicate that at low lift coefficients the addition of end plates increased the slope of the lift curve, reduced maximum lift-drag ratio, generally decreased maximum lift coefficient, and increased longitudinal stability. It was also found that the variation of effective dihedral with lift coefficient for the wing-end plate combinations investigated was reduced by an increase in the size of the end plate.

A knowledge of the character of the downwash fields behind wings is required for the rational design of horizontal tail surfaces as well as for the analysis of the longitudinal stability characteristics of an airplane. One theoretical study of this problem has resulted in the development of a method for calculating the downwash field behind lifting surfaces at subsonic and supersonic speeds. A description of the method, together with an illustrative example of its use, is contained in Technical Note 2344. In connection with another study, a series of charts and tables was prepared from which the downwash behind horseshoe vortices in incompressible flow can be obtained. The use of these charts and tables in connection with the calculation of the downwash behind wings of arbitrary planform is

described in Technical Note 2353, which also contains illustrative examples. Report 983 describes the use of line vortex theory for the calculation of supersonic downwash and Technical Note 2141 contains charts for the estimation of downwash behind rectangular, trapezoidal, and triangular wings which were prepared on the basis of line vortex theory.

Studies of Dynamic Stability

At the Ames Laboratory the dynamic lateral stability characteristics of a dive-bomber type of airplane were investigated in flight to determine the cause of a small amplitude continuous motion referred to as "snaking." The results of this investigation, reported in Technical Note 2195, indicate that the floating characteristics of the rudder were affected by Mach number and had an appreciable effect on the snaking of the airplane. Rudder modifications resulting in an increase in the restoring tendency of the rudder proved successful in eliminating this undesirable lateral oscillation.

The effects of control centering springs on the apparent spiral stability characteristics of a typical high-wing personal-owner airplane have been investigated in flight. Control centering was provided for both the ailerons and rudder by means of preloaded springs. Results of the investigation, reported in Technical Note 2413, show that the airplane appeared to be spirally unstable with controls free when the centering springs were disengaged because of moments resulting from out-of-trim control position. With centering springs engaged, however, the airplane quickly returned to straight and level flight with the controls freed following an abrupt disturbance. The report also includes information concerning the flying qualities of the airplane in rough air.

At the Langley Laboratory free-flight-tunnel studies were made to determine the effects of mass distribution on the low-speed dynamic lateral stability and control characteristics of a free-flying model. In this investigation the longitudinal and lateral mass distributions of the model were varied, both independently and simultaneously, while the relative density factor was held constant. The results of the investigation, presented in Technical Note 2313, show that increases in the rolling and yawing moments of inertia reduced the controllability of the model by increasing the time required to reach a given angle of bank and caused the flying qualities to become less desirable. The study also showed that, as moment-of-inertia increased, the oscillatory stability generally decreased and flight behavior became progressively less satisfactory.

A study has been made of methods for the evaluation of dynamic stability parameters from flight-test data. The ability to evaluate these parameters by this tech-

nique will make it possible to obtain information on the variation of these factors in the critical transonic range. The results of this study are reported in Technical Note 2340 and mathematical aids for the analysis presented in this paper are reported in Technical Note 2341.

A summary of available methods for estimating subsonic dynamic lateral stability and airplane response characteristics and for estimating the aerodynamic stability derivatives required in these calculations has been made. The results of this summary are presented in Technical Note 2409. This paper presents methods for obtaining time histories of lateral motions, period and damping characteristics, and the lateral stability boundaries, and also provides references to related experimental data. A brief discussion of the evaluation of transonic and supersonic stability parameters is included.

A matrix method has been derived to determine the longitudinal stability coefficients and frequency response characteristics of aircraft from arbitrary maneuvers. This method is presented in Technical Note 2370 and can be applied to time history measurements of such quantities as angle of attack, pitching velocity, load factor, elevator angle, and hinge moment to obtain over-all coefficients. With simple additional computations, it can also be used to determine frequency response characteristics and may be applied to other problems expressed by linear differential equations.

A theoretical investigation was made using LaPlace transformations to determine the effect of nonlinear stability derivatives on airplane lateral stability characteristics, with particular emphasis placed on snaking. The nonlinearities assumed corresponded to the condition where values of the directional stability and damping-in-yaw derivatives are zero for small angles of sideslip. Results of this study are presented in Technical Note 2233 and indicate that under certain conditions the assumed nonlinearities caused a motion which had different rates of damping for large and small amplitudes and little damping at the small amplitudes.

Another theoretical study was made to determine the effects of fuel motion on airplane dynamics. Results of this study are presented in Technical Note 2280. In this report, the general equations of motion for an airplane with spherical fuel tanks are presented. The motion of the fuel is approximated by the motion of solid pendulums. The analysis applies to fuel tanks of any shape if the fuel motion can be represented in terms of undamped harmonic oscillators. The study shows that fuel motion may have an appreciable effect on the dynamic behavior of an airplane.

Analytical and experimental investigations have been made to determine the effects of wing interference on

vertical tail effectiveness at low speeds. These studies have been reported in Technical Notes 2332 and 2175. Comparisons of the estimated and experimental results indicate that the inclusion of a factor to account for wing interference effects provides agreement between the experimental and estimated values of the tail contribution to the rolling derivatives.

The lift and pitching moment produced by angle of attack, steady state pitching, and constant vertical acceleration for a series of thin sweptback streamwise-tip wings of arbitrary sweep and taper have been determined through the use of linearized supersonic flow theory. The method of analysis and the results from the angle of attack and steady state pitching studies are presented in Technical Note 2294 for a range of supersonic Mach numbers that allow the wing leading edge to be subsonic and the trailing edge to be either supersonic or subsonic. The method of analysis and studies of the lift and pitching moment due to constant vertical acceleration are reported in Technical Note 2315 for a range of supersonic Mach numbers for which the wing leading edge is subsonic and the trailing edge supersonic. Design charts are presented in both of these reports that permit rapid estimates of wing lift and pitching moment for given values of aspect ratio, taper ratio, Mach number, and leading-edge sweep.

Automatic Stability Studies

The application of automatic controls to the operation of aircraft complicates the analysis of aircraft dynamics. In order to gain a more thorough knowledge of the factors involved in the automatic control and stabilization of airplanes and missiles, research has been intensified on means of solving current and anticipated problems in this field.

A survey has been made of various techniques used in analysis of the stability and performance of automatically controlled aircraft. This survey deals with methods commonly applied to the linear, continuous control type of system ordinarily used in aircraft, and has been published as Technical Note 2275.

An investigation was carried out to evaluate the suitability of proposed methods for analyzing servomechanism systems incorporating feedback. This study is described in Technical Note 2373 and deals with an extension of frequency response techniques for the analysis of an autopilot-aircraft combination. This paper contains comparisons between experimental data and results obtained by the use of the practical methods of calculation which were developed.

An experimental investigation was conducted to determine the response characteristics of four airplane configurations employing an autopilot sensitive to yawing acceleration. The results of this study are pre

sented in Technical Note 2395 and show that predictions based on the assumed autopilot characteristics did not agree with experimental data because the assumptions did not satisfactorily approximate the frequency response characteristics of the autopilot.

A theoretical method was derived for determining the control gearings and time lags necessary for a specified damping of the lateral motions of an aircraft equipped with an autopilot. The method was applied to a typical airplane equipped with an autopilot which deflects the rudder in proportion to yawing angular acceleration. The results of this study, presented in Technical Note 2307, indicate that the types of motion predicted for this airplane-autopilot system by the derived method are in good agreement with those obtained by a step-by-step method.

Research on Controls

Theoretical and experimental research on the effects of numerous control design variables on the characteristics of controls has been continued during the past year.

In one theoretical study, an analysis was made of the effects of sweep, aspect ratio, taper ratio, and Mach number on the characteristics of inboard trailing-edge flaps at supersonic speeds. This study considers cases where the Mach lines lie behind the leading and trailing edges of the flap. Design charts developed from the analysis and presented in Technical Note 2205 enable a rapid estimation to be made of the characteristics due to deflection for control surfaces for which the Mach lines from the flap tips do not intersect on the control surface.

In another theoretical analysis, supersonic control characteristics were determined through the use of existing conical-flow theory. This analysis applies to a broad range of trailing-edge control configurations having supersonic edges and covers such variables as wing aspect ratio, taper ratio, sweep and control location. The results of this study, presented in Technical Note 2221, are in the form of equations and charts from which lift, pitching-moment, rolling-moment, and hinge-moment coefficients may be determined.

The stability and control characteristics of wings of trapezoidal planform were investigated by means of linearized supersonic theory to determine the characteristics of various wing-flap combinations. Expressions for the stability characteristics were derived by treating the configuration as a complete wing, and the control characteristics were determined by treating it as a rectangular wing with half-delta tip flaps. The results, reported in Technical Note 2336, were compared with corresponding results for several other wing-flap combinations and it was found that, of the wings con-

sidered, a triangular wing with either half-delta tip flaps or trailing-edge controls exhibited the most favorable characteristics.

As part of the general NACA program to investigate the applicability of various types of lateral control devices to wings suitable for high-speed flight, an experimental investigation was conducted in the Langley 300-mph 7- by 10-foot tunnel to determine the effect of aspect ratio on the lateral control characteristics of a series of untapered, unswept, low-aspect-ratio wings equipped with continuous type retractable spoiler ailerons. One swept wing was included in the study for purposes of comparison, and, in addition to being equipped with the continuous type spoiler, was also investigated when equipped with a stepped or segmented spoiler aileron. The results of the study, reported in Technical Note 2347, indicate that for the unswept wings continuous spoiler ailerons became progressively more effective in producing roll as wing aspect ratio was increased. The continuous spoiler aileron was less effective on the swept wing than on a straight wing of comparable aspect ratio. On the swept wing it was found that the effectiveness of the continuous spoiler generally increased as the spoiler was moved progressively inboard, while the opposite was true for the stepped spoiler.

An experimental investigation was conducted in the Langley 300-mph 7- by 10-foot tunnel to determine the lateral control characteristics of an untapered semispan wing having either 0° or 45° of sweep and equipped with a plain unsealed aileron. The span and spanwise location of the aileron were varied in order to determine the optimum configuration for rolling effectiveness. The results of this investigation, reported in Technical Notes 2199 and 2316, indicate that for either the swept or unswept wing, a given partial span aileron was most effective in producing roll and in maintaining effectiveness over a large angle of attack range when located on the outboard portion of the wing. It was also found that, although the rate of change of aileron hinge-moment coefficient with angle of attack could not always be satisfactorily predicted for the swept wing, existing empirical methods for predicting the rate of change of rolling moment coefficient and aileron hinge-moment coefficient with aileron deflection provided satisfactory agreement with the experimental results for both the straight and swept wings.

In order to determine the effect of aspect ratio on the low-speed lateral control characteristics of low-aspect-ratio wings, a series of four unswept, untapered wings with aspect ratios from 1 to 6 was investigated in the Langley 300-mph 7- by 10-foot tunnel. The wings were equipped with plain sealed ailerons of various spans located at several spanwise stations. The results of this study are presented in Technical Note 2348 and

show that the variation of aileron effectiveness with aspect ratio could not be accurately predicted for all aileron spans by any of the theoretical methods utilized in this investigation.

Studies of Damping Derivatives

Theoretical and experimental studies have been extended in the past year to develop methods for the reliable evaluation of damping derivatives in all speed ranges.

One theoretical method, described in Technical Note 2197, was developed for calculating the pressure distribution and damping in pitch at supersonic Mach numbers for thin swept wings having subsonic edges. The method consists of the calculation of a basic pressure distribution and the correction of this distribution to account for the effects of the subsonic trailing edges and tips. These data are then used to determine the damping-in-pitch characteristics.

Technical Note 2285 presents an evaluation of the supersonic damping in roll of cruciform delta wings by means of linearized theory. Both subsonic and supersonic leading edges were considered. The effect of increasing the number of wing panels from four to an arbitrary number under the restriction of low-aspect ratio was determined, and the damping for an infinite number of wing panels was evaluated without restriction as to aspect ratio or Mach number. A similar theoretical study is reported in Technical Note 2270 in which the theory of slender wings was used to determine the characteristics in roll of slender cruciform wings. This analysis shows that, for the cruciform wing, the damping-in-roll is considerably greater than that of a plane wing having the same aspect ratio and that the rolling effectiveness is less than that of a plane wing.

Experimental studies of damping derivatives have been carried out in the rolling and curved flow facilities of the Langley stability tunnel. One investigation was conducted to determine the effects of horizontal tail location on the low-speed static longitudinal stability and damping in pitch of a model with 45° swept wings and tail. The results, published in Technical Note 2381, indicate that at high angles of attack, lowering the horizontal tail increased the static longitudinal stability and decreased the damping in pitch. A related investigation is reported in Technical Note 2382. In this study, horizontal tail size and tail length are variables. The study shows that the contribution of the horizontal tail to static longitudinal stability was directly related to tail size and length, while damping in pitch was related to tail size and the square of the tail length.

Another investigation was conducted in the Langley stability tunnel to determine the effect of vertical tail

area and tail length on the yawing stability of a model with a swept wing. Technical Note 2358 contains the results of this study, which indicate that the effects of wing-fuselage interference for the midwing configuration studied were small over most of the angle-of-attack range. Large interference effects on the vertical tail effectiveness were apparently produced by both the wing and fuselage at moderate and high angles of attack, but because these effects tended to cancel each other, the gross effects were small.

Investigation of Flying Qualities

The increasing operational speeds of current and proposed aircraft have aggravated the problems involved in defining and achieving flying qualities compatible with safety, performance, and piloting requirements. Research to isolate the effects of numerous design parameters on flying qualities has continued to receive attention.

Two design factors which can significantly affect the flying qualities of an airplane are the wing airfoil section and the type of lateral-control device employed. To determine the effects of one of these design variables on the flying qualities of an airplane model, an investigation was conducted in the Langley free-flight tunnel to determine the effects of round and sharp leading-edge airfoil sections on the dynamic lateral stability and control characteristics. Two models were used in the study, one representative of a current fighter airplane with respect to inertia characteristics and the other representative of a possible future design in which mass is concentrated along the fuselage. The results of the investigation, reported in Technical Note 2219, indicate that airfoil section has no apparent effect on the flying qualities of the model with high fuselage inertia. The normal inertia model when equipped with the wing having a round-nose airfoil section exhibited adverse yawing during aileron rolls which increased with decreases in directional stability. This same model, however, exhibited no adverse yawing when fitted with the wing having a sharp-nose airfoil, even at low values of directional stability. This difference in flying characteristics is attributed to the adverse yawing moment due to rolling of the round-nose wing, which on the other model is apparently masked by the high fuselage inertia.

Another investigation was conducted in the Langley free-flight tunnel to compare the dynamic lateral-control characteristics of stepped plug ailerons with those of conventional plain flap ailerons. The model employed in this study had a low-aspect-ratio swept wing equipped with full span flaps. The results of the investigation, published in Technical Note 2247, show that when the lateral stability characteristics were satisfactory the controllability of the model was better with

plug ailerons alone than with conventional ailerons alone because the loss of rolling effectiveness due to the adverse yaw associated with the flap aileron was more objectionable than the lag associated with the plug ailerons. For conditions of low dynamic lateral stability, the conventional ailerons alone provided better controllability than either plug ailerons alone or a combination of flap ailerons and rudder. Although the time lag of the plug ailerons was excessive according to existing flying qualities requirements, the pilot considered the controllability of the model to be satisfactory.

The improvement of passenger comfort in airplanes, through a reduction of accelerations caused by rough air, has become of greater interest as airplane operational speeds have increased. One method which has been suggested for providing increased comfort in high-speed airplanes is to have the wing flaps operated by an angle-of-attack or acceleration-sensing device in such a manner as to reduce accelerations due to gusts. A theoretical study of such a system has been made and is reported in Technical Note 2416. The results of the study show that flaps with characteristics similar to those of conventional landing flaps are unsuitable for acceleration alleviation because of airplane pitching motions resulting from flap deflection. The analysis indicates that the flaps should produce zero pitching moment about the wing aerodynamic center and downwash at the tail in the opposite direction from that normally expected in order to be satisfactory for this application. Various means of achieving these characteristics are suggested, and it is shown that flaps possessing these desirable characteristics would be effective in reducing accelerations in rough air when combined with an angle-of-attack or acceleration-sensing device.

In the previous study no attempt was made to consider the practical problems involved in the design of a mechanism for acceleration alleviation. To help evaluate one of these problems, an experimental investigation was made to determine the ability of a vane mounted ahead of the nose of an airplane to give an indication of the average angle of attack over the entire wing span during flight through rough air. The results of this investigation are presented in Technical Note 2415 and show that the device gives a sufficiently accurate indication of average angle of attack over the wing span to allow its use in an acceleration alleviation system.

Spinning Investigations

The spin and recovery characteristics of airplanes are dependent on many aerodynamic and structural design parameters. In order to provide the designer with information on which of these parameters may be of primary importance to the recovery characteristics of

any particular aircraft configuration, research on the problems of spinning has continued in the Langley 20-foot free-spinning tunnel.

One investigation was conducted to determine the effects of mass and dimensional variations on the spin and recovery characteristics of a model representative of current four-place light airplanes. The results, which are reported in Technical Note 2352, indicate that satisfactory recovery characteristics could be obtained for all of the mass distributions studied provided that the proper sequence of control movements for recovery was followed. It was also found that unless the rudder can be made to float against the spin, recovery by releasing controls may be difficult to achieve unless the elevator floats below neutral. Other requirements for spin recovery set forth in current regulations could probably be met for the model arrangements investigated by restricting center-of-gravity location and providing a high value of tail damping.

Because a previous study had indicated that a horn-balanced rudder might possess the desirable characteristic of floating against the spin, an experimental investigation was undertaken to determine the floating characteristics of full-length plain and horn-balanced rudders during rotary tests at spinning attitudes of a model of a typical low-wing light airplane. The effects of the horizontal tail and wing on the rudder floating characteristics were also determined. The results of this investigation, reported in Technical Note 2359, indicate that for this configuration the rudder was in the wake of the stalled wing and oscillated violently for high spinning angles of attack. At lower angles of attack, or for the case in which the tail was outside the wake of the stalled wing, the horn-balanced rudder had more desirable floating characteristics than a plain rudder, although neither would fulfill the floating deflection requirements for control-free spin recovery.

AIRCRAFT PROPELLERS

In the field of propeller vibration, Technical Note 2308 has been published in continuation of the investigation of first-order propeller vibration on a twin-engine, straight-wing airplane in the Ames 40- by 80-foot tunnel. A procedure has been developed for computing the flow field at the propeller plane to a sufficient degree of accuracy to permit satisfactory calculation of the propeller vibratory stresses. In the procedure, account is taken of the upwash contributions of the wing, fuselage, and nacelles and their mutual interference effects. The analysis shows that the nacelle caused an unexpectedly large effect which, if ignored, could readily cause disagreement between the magnitude of computed and measured vibratory stresses.

In another propeller vibration investigation, the existing analysis applicable to the prediction of first-order exciting forces for the straight-wing propeller case has been extended to include the swept-wing propeller combination. With the aid of the straight-wing analysis, a typical swept-wing propeller-driven airplane design has been studied to examine the magnitude of the once per revolution exciting forces which could exist. It has been found that in addition to the usual exciting forces, a new and relatively important one is added where a swept wing is used; this results from the relative fore and aft movement of the propeller blade with respect to the leading edge of the wing which is swept with respect to the propeller plane of rotation. It was found further that the effects of Mach number are such as to reduce the magnitude of the once-per-revolution exciting forces.

SEAPLANES

Hydrodynamic studies have continued in the Langley tanks to provide basic and design data for the development of water-based airplanes.

One study reported in Technical Note 2297 investigated the use of high angles of dead rise on high-length-beam-ratio flying-boat hulls as a means for reducing water loads encountered during rough-water operation. An increase in angle of dead rise from 20° to 40° increased the take-off stability and substantially improved the spray characteristics of a high-length-beam ratio hull. An expected decrease in take-off performance was evidenced by increases in take-off time and distance of 25 and 30 percent, respectively. The over-all rough-water landing behavior was improved; the maximum vertical and angular accelerations were reduced approximately 55 and 30 percent, respectively. The reduction in vertical acceleration was in good agreement with that predicted by impact theory.

ROTARY WING AIRCRAFT

Based on the results of flight investigations of several single-rotor helicopters, preliminary qualitative requirements for satisfactory flying and handling qualities of helicopters have been established. Progress in designing helicopters to meet these requirements, however, has been handicapped by the need for a method permitting sufficiently accurate prediction of the flying qualities of a helicopter at the design stage. To help fill this need, existing rotor theory, accurate for the calculation of rotor performance and blade motion, has been extended (Technical Note 2309) to permit the prediction of those rotor characteristics that influence the flying qualities. Variation of the longitudinal derivatives of rotor resultant force, rotor pitching mo-

ment, and rotor torque with operating parameters such as rotor angle of attack, collective pitch, forward speed, and rotational speed may be determined. The usual simplifying assumption that the rotor resultant force vector is perpendicular to the rotor tip path plane is shown by the results of this theory to lead in many cases to grossly incorrect longitudinal stability derivatives. The theory also indicates that the increase in rotor load factor with an incremental increase in angle of attack is approximately linear with increasing forward speed. This is in contrast to the airplane where the increase is as the square of the forward velocity.

Increases in the forward speed of helicopters are expected to require increases in rotor tip speeds in order to avoid excessive tip stalling on the retreating blade. At tip speeds within the transonic range the rotor will suffer some performance loss due to compressibility. In order to gain an insight into the magnitude of this compressibility-induced performance loss and to furnish a check on theoretical methods of estimating the loss, two conventional full-scale rotors, one having linear twist and the other untwisted, have been tested to tip speeds up to 770 feet per second on the Langley helicopter test tower. The results of this study, reported in Technical Note 2277, show that both rotors suffered increasing compressibility losses as the tip speed increased to the maximum speed studied. Linear twist delayed the onset of compressibility losses. For the blades investigated good agreement was obtained between the measured and predicted drag-divergence Mach number.

As part of a general investigation of the aerodynamic characteristics of various multirotor configurations, an investigation to determine the static-thrust performance of two full-scale coaxial helicopter rotors has been conducted in the Langley full-scale tunnel. One coaxial rotor was equipped with blades tapered in both planform and thickness and the other with blades tapered in thickness only. The results, presented in Technical Note 2318, show the hovering performance of each rotor in the coaxial configuration and with the upper rotor removed. The effect of application of yaw control on the hovering performance of the coaxial configurations is also presented. A comparison of measured and predicted hovering performance is included.

As a part of the investigation of multirotor configurations a study was made of the air-flow patterns through small scale single, coaxial, and tandem rotor models. The balsa-dust technique of air-flow visualization was employed. The photographic results, presented in Technical Note 2220, provide a qualitative interpretation of the transient and steady-state flow through the rotors.

A theoretical study of the rigid-body oscillations in hovering of helicopter rotor blades has been made by

the Polytechnic Institute of Brooklyn under NACA sponsorship. The study, presented in Technical Note 2226, includes a determination of the rigid-body frequency and damping characteristics of the coupled flapping and lagging oscillations of helicopter blades on which the lagging hinge axis is offset from the flapping hinge axis and both hinges are inclined. The effect of offset of the flapping hinge axis from the axis of rotation of the rotor is also considered.

The analysis and numerical examples indicate that significant increases in the damping of the lagging motions, which ordinarily border on instability, can be obtained by suitable inclinations of the hinge axis, particularly the lagging axis. Offsetting the flapping and lagging hinge axis also increases the natural lagging frequency.

UPPER ATMOSPHERE RESEARCH

The study of the compatibility of the tentative standard atmospheric temperature distribution as set forth

in Technical Note 1200 with the observed free periods of oscillation of the atmosphere has continued. Technical Notes 2209 and 2314 present the results of a continued study of atmospheric tides by the Institute for Advanced Study, under NACA sponsorship. The investigations indicate that certain simplifying assumptions made in the development of the basic ocean tide equations invalidates these relations for application to the study of atmospheric tides. A method for including the previously neglected terms in the tidal equations has been outlined and two atmospheres of different temperature distribution have been studied.

A review by the Subcommittee on the Upper Atmosphere of experimental information on the characteristics of the atmosphere from sea level to a height of 32 kilometers has indicated that the standard atmosphere tentatively proposed in Technical Note 1200 represents to a satisfactory degree of accuracy the characteristics of the atmosphere within this height range.

POWER PLANTS FOR AIRCRAFT

With the ever-increasing trend for aircraft operation at higher altitudes and higher Mach numbers there has arisen a multitude of complex power plant problems. Efficient diffusers at high Mach number, greater air flow handling ability of compressors, increased combustion efficiencies at high altitudes without blowout or instability, increased turbine inlet gas temperatures, reduction of strategic material content, increased thrust augmentation with afterburners, and the over-all engine control and component matching require extensive power plant research. For the purpose of obtaining the most efficient operation of each part of the power plant, these problems have been approached through theoretical and experimental investigations. Power plants, such as the turbojet, the turbopropeller, the ram jet, the rocket, and combinations of these engines utilizing chemical and nuclear fuels are currently under investigation. As a result of this research improved subsonic and supersonic operation of the interceptor, the long-range bomber, and the guided missile can be expected.

NACA efforts in the aircraft-propulsion field have been assisted by the Committee on Power Plants for Aircraft and its seven subcommittees. The following discussion is limited to unclassified research.

AIRCRAFT FUELS RESEARCH

Intensive effort has been applied in the past year to the field of aircraft-fuel research with consideration being given to current aircraft fuels as well as fuels of the future. As might be expected, investigations conducted since the advent of jet propulsion have gradually led toward the development of special fuels for future

power plants. Concurrently with research on future fuels it has been necessary to maintain a high degree of emphasis on current aircraft fuels in order to assure the availability of satisfactory fuels in the event of an emergency. The greatest problem in the current aircraft-fuel program is the formalization of a sound fuel specification that will assure maximum availability and superior performance.

Synthesis and Analysis

Because many of the aircraft considered for the future are volume-limited with respect to fuel storage, hydrocarbon synthesis has been directed primarily toward fuels that will release high energy per unit volume and consequently permit the attainment of desired flight range. Fuels of this type are not readily available even in small quantities required for research studies. For this reason synthesis facilities of the NACA are in continuous operation isolating pure high-density hydrocarbons to be used in engine-performance studies.

During the past year the synthesis and purification of some of the high-density hydrocarbons have been described in Technical Notes 2230 and 2260. Nineteen compounds were isolated and those having satisfactory physical and chemical properties will ultimately be evaluated in typical turbojet-combustor performance investigations. The synthesis projects are planned in an orderly manner to permit the analysis of correlations between molecular structure and properties. By this process considerable time and money is saved in that an examination of the correlation will indicate

which molecular structures have obvious disadvantages, thus obviating costly and tedious synthesis.

In addition to high-density hydrocarbons, other compounds have been synthesized for investigation as possible fuel components to provide greater combustion stability over wide operating ranges and better ignition characteristics. Hydrocarbons such as cyclopropane derivatives are being prepared for study of the effect of molecular structure on rates of flame propagation. Results of the synthesis of ten cyclopropane hydrocarbons have been reported in Technical Notes 2258, 2259, and 2398. The ten hydrocarbons were obtained in high purity for the first time and physical constants and infrared spectra are given in the cited references. Synthesis procedures were developed, and physical properties and heats of combustion were determined for four alkylsilanes. This was the first experimental determination of heats of combustion for these compounds.

In the course of conducting synthesis projects, occasional results of general interest with regard to experimental technique are obtained. When this occurs, the data are published for the information and use of various synthesis laboratories. A study of this nature has recently been reported in Technical Note 2342. In this publication an evaluation of packed distillation columns used by the NACA is described.

Aside from the determination of physical properties of synthesized materials, the NACA analytical laboratories participate in studies to improve methods of analysis of fuels. Particular attention has been given to the analytical procedure for determination of aromatic and olefinic hydrocarbons in wide-boiling petroleum fractions. These hydrocarbon classes are known to be significant in relation to engine performance and therefore the quantities present in a given fuel stock must be accurately known. A procedure for the determination of aromatics and olefins has been developed which is applicable to the determination of aromatics and olefins in petroleum stocks with final boiling points below 600° F. Accuracies of 1 percent are attained with analysis times of less than 8 hours.

Fuels Performance Evaluation

The problem of relating easily measured hydrocarbon fuel properties to engine performance has received considerable attention since the advent of jet propulsion. The object of this research is to permit the prediction of engine performance of fuels from fuel properties that may be determined with relative ease. Combustion properties of interest are spontaneous ignition temperature, flame velocities, and inflammability limits.

Spontaneous ignition temperatures for 109 hydrocarbons and commercial fuels have been determined by a crucible method. From these data trends in the varia-

tion of ignition temperature with molecular structure have been established. The performance of ten of these fuels has been studied in a single tubular combustor.

During the past year flame-velocity studies were made of 37 pure hydrocarbons. The classes of compounds examined were alkanes, alkenes, alkynes, benzene, and cyclohexane. The results of this study indicated that the flame velocities of the normal alkanes were the same except for methane which had a velocity about 16 percent lower than the alkanes of higher molecular weight. The alkenes and the alkynes had velocities somewhat higher than those of the alkanes, particularly in the low molecular weight range. The results of this investigation have been published in the *Journal of the American Chemical Society* (vol. 73, No. 1, January 1951).

The flame velocity investigation was later extended to include the alkadienes. Ten compounds in this class were studied and it was found that the flame velocities were higher than those of the alkanes and approximately equal to the flame velocities of the alkynes investigated. Performance of certain fuels in these classes of compounds are being studied in a single tubular combustor.

The flame-velocity data accumulated in the foregoing investigations have been used as the basis for correlations between molecular structure and flame velocity. One such correlation indicated that the maximum flame velocity is a function of the concentrations of the various types of carbon-hydrogen bonds in the inflammable mixture. From this correlation the maximum flame velocities were calculated for 34 hydrocarbons. The average difference between the calculated and observed flame velocity is less than 2 percent. The results of this analysis were published in the *Journal of the American Chemical Society* (vol. 73, No. 4, April 1951).

As another part of this research an investigation is being conducted to determine the inflammability limits of pure hydrocarbon-air mixtures at different pressures. The limits were determined for 17 pure normal paraffins, branched paraffins, and mono-olefins. It was found that the lean inflammability limits were about the same for all of the fuels, however, the rich limits increased markedly with increased molecular weight.

The tendency of certain fuels to deposit carbon in combustors thereby lowering performance and causing mechanical difficulties continues as one of the more important problems for research. Brief investigations have been made of several fuels which contain components allowable in the jet fuel specification but which appear marginal from a carbon deposition standpoint. A study of these fuels with several current turbojet engines is intended to show how fuel specification and combustor design may be compromised for best performance and maximum fuel availability.

COMBUSTION RESEARCH

Because aircraft engines must produce enormous power from a small package, it is axiomatic that the combustion problem is to release tremendous quantities of heat energy from the fuel in a small volume and in a short space of time. NACA research on combustion is directed at obtaining an understanding of the basic physics and chemistry behind the phenomena involved in combustion and demonstrating how these phenomena can be put to use to meet all the requirements of flight. Basic studies are made on detailed problems of combustion such as evaporation, ignition, flame propagation limits, flame velocity, flame quenching, with variables such as composition, pressure, temperature, velocity, and turbulence. Studies on applying these data involve (a) systematic studies of the effect of operating variable and design variables on engine performance such as combustion efficiency, altitude operational limits, smoke and carbon formation, pressure drop and temperature profile, and (b) attempts to correlate basic combustion laws with engine performance.

Fundamentals of Combustion

To gain an insight into the problem of combustion stability at high altitudes, a study has been made of the chemical and physical factors affecting the inflammability limits at different pressures. The results of the investigation of chemical factors were discussed under the fuels research program. An investigation was also made of the effects of walls on inflammability limits. The results indicated that the minimum pressure for flame propagation increased with diminishing tube diameter (greater relative wall area). In connection with the inflammability limits of fuels, an investigation was conducted to determine the combustion efficiencies of hydrocarbon-air systems at reduced pressures. With quiescent fuel-air mixtures and with small diffusion flames, combustion efficiencies close to 100 percent were obtained at pressures much lower than those found in turbojet combustors at high altitude; in general, efficiencies were high at pressures approaching the limiting values for inflammation.

Several projects are in progress to ascertain the basic mechanism of flame propagation in order to gain insight into the actual combustion process that occurs in an engine. These studies supplement the studies of the effect of hydrocarbon structure on flame velocity reported in the fuels program. In one phase of this work, the effect of initial mixture temperature on flame velocity was evaluated. The first of these studies (Technical Note 2170) evaluated the flame velocities and blow-off limits of propane-air flames. These studies

were later extended to include methane-air and ethylene-air flames (Technical Note 2374). As a result of these projects, equations were developed to permit the estimation of flame velocity at various initial mixture temperatures in the range of 34° to 344° C.

In order to achieve a better understanding of the cause of flame propagation, several studies have been made of the effect of free radicals on flame propagation. Inasmuch as hydrogen diffuses more readily than other radicals in a flame, it has been suggested by past investigators that the rate of flame propagation is related to the hydrogen-atom concentration in the flame zone. An evaluation of this theory was made by adding light water and heavy water to mixtures of carbon monoxide and air and measuring the flame velocities. It was reasoned that hydrogen from heavy water would diffuse less rapidly than that from light water; consequently, a lower flame velocity would result. Measurements of the flame velocities substantiated this reasoning.

In an analysis of flame-velocity data for 35 pure hydrocarbons, it was concluded that the maximum flame velocities were consistent with the active radical theory of flame propagation. Only one pure hydrocarbon, ethylene, was found to be inconsistent with the theory. This analysis was published in the Journal of the American Chemical Society (vol. 73, No. 1, January 1951).

In connection with flame-velocity investigations, a method for determining the distribution of luminous emitters in a Bunsen flame was found and is described in Technical Note 2246. As an example of the application of this method, an intensity distribution in a Bunsen cone image resulting from the free radical C_2 radiation was analyzed.

In order to correlate the flame-propagation velocities of a burner with the local turbulence intensity in the flow, quantitative turbulence data are needed. Such data have been obtained from an investigation, the results of which are presented in Technical Note 2361. Data were obtained for turbulent-velocity-fluctuation components and mean-velocity distributions in a subsonic jet issuing from a pipe in which fully developed turbulent flow was established. It was found that at the jet exit the axial-fluctuation-velocity component was about 2.5 times as great as the radial component at the pipe center line. Near the pipe wall, the axial-fluctuation-velocity component was about three or four times as great as the radial component. The axial components of the turbulent fluctuation velocities diminished rapidly downstream of the pipe wall, whereas the radial components were practically constant so that the axial and radial components approached a condition of equal magnitude with increasing distance from the pipe exit

LUBRICATION AND WEAR

Fundamentals of Friction and Wear

The current trend in the selection of aircraft-power-plant lubricants is to materials of low viscosity. The primary reason for this is to meet low temperature operating and starting requirements. It may be expected that such usage will lead to difficulties because of the low load capacities obtained with the light oils. One means of compensating for the reduced load capacity is by the use of EP (extreme pressure) additives. One of the objectives of lubrication and wear research is to determine for surfaces lubricated with EP additives whether a change in chemical reactivity could appreciably affect the rate of production of a protective film and thus appreciably affect the critical sliding velocity at which surface welding begins. Among the additives under study are benzyl chloride $C_6H_5CH_2Cl$, p-dichlorobenzene $C_6H_4Cl_2$, free sulfur S, benzyl disulfide $(C_6H_5CH_2)_2S_2$, and phenyl monosulfide $(C_6H_5)_2S$, at sliding velocities from 75 to 7,000 feet per minute and initial Hertz surface stresses up to 194,000 p. s. i. (Technical Note 2144). Results indicate that higher critical sliding velocities may be obtained with additives whose active atoms have the greatest chemical reactivity. The study showed that the factor of activity of the individual active atoms was more important than the number of such atoms available for reaction.

A further study of the effect of additives on critical sliding velocities involved the use of fatty acids (Technical Note 2366). This investigation was conducted because it has been found that with an EP additive lubrication may be ineffective at high sliding velocities because a chemical reaction between the surfaces and the additive to provide a lubricating film may not have time to occur. Further, studies at low temperatures have established the point that with the fatty-acid additive, high contact temperatures or pressures are unnecessary for the formation of an effective lubricating film. Studies have been completed of stearic acid as an additive in cetane at sliding velocities up to 7,000 feet per minute on clean steel surfaces and surfaces coated with ferric oxide Fe_2O_3 (Technical Note 2366). The experiments indicate that the type of surface oxide and the thickness of the oxide film are important in determining the effectiveness of stearic acid as an additive.

Most of the bearings employed in the turbine-type aircraft power plants are rolling-contact bearings. Early service experience indicated that one of the principal sources of failure in bearings has been lubrication failures at the cage locating surfaces (retainer or separator). These failures are due in main to the difficulty in obtaining proper lubrication because of design con-

figurations and to "high-temperature soaking" (above 500° F.) of the turbine bearing after engine shut-down. One means of reducing the severity of the problem is to obtain a cage material having a lesser tendency toward metallic adhesion to steel under marginal conditions of lubrication than the currently used materials. Sliding friction experiments have been made to obtain fundamental comparative information on friction and wear properties which are a general measure of adhesion (Technical Note 2384). The materials studied were brass, bronze, beryllium copper, Monel, Nichrome V, 24S-T aluminum, nodular iron, and gray cast iron at sliding velocities up to 18,000 feet per minute. On the basis of wear and resistance to welding only, the cast irons were the most promising materials investigated in that they showed the least wear and the least tendency to surface failure when run dry. On the basis of mechanical properties, the nodular iron is superior to gray cast iron. Results obtained with brass, beryllium copper, and aluminum indicate that these materials are not particularly suited for cages.

It has been observed that the running of piston rings, particularly nitrided cylinder barrels, induces the formation on the ring of a surface coating which had different and, in some respects, superior properties compared with those of the bulk ring material. An investigation has been completed, whose objective was to determine to what extent these rubbing conditions could have produced transfer of metal from the barrel to the ring (Technical Note 2271). The study concerned itself with metal transfer between nitrided steel of several hardnesses and also between chromium plate and nitrided steel. The technique employed consisted of making one of two rubbing surfaces radioactive, carrying out a friction test and then examining the other surface for signs of radioactivity. The effects on material transfer of, load, speed, distance of travel, repeated travel over the same path, hardness of the moving surface, and the type of chromium plate were investigated. In the case of all materials studied, there was an observable amount of transfer. The amount of transfer was roughly proportional to the distance traveled and was independent of whether this travel was repeated a number of times over the same track or was continuously over fresh surface. In addition, the amount of transfer for a given distance of travel was constant over a range of low speeds, but started to decrease at higher speeds. This indicates that a possible pretreatment to obtain a desirable surface layer might consist of running rings in a special cylinder having walls of selected composition and controlled hardness to give surface coatings highly improved characteristics in a minimum length of time.

Fretting

Fretting is defined as the surface failure that may occur when closely fitting metal surfaces undergo slight relative motion. Recent research conducted by the NACA indicates that fretting is the result of localized or very concentrated friction phenomena. Adhesion is believed to be the primary friction phenomenon involved in that it causes the removal of finely divided oxidizable metal. Other phenomena, such as the rubbing off of oxide films, welding from frictional heat, and abrasion, undoubtedly contribute to surface destruction. The effectiveness of the intermetallic compound molybdenum disulfide (MoS_2) as a fretting inhibitor was studied, utilizing a steel ball, vibrated in contact with glass flats at 120 cycles per second, an amplitude of 0.001 inch, and a normal load of 0.2 pound (Technical Note 2180). A coating of dry molybdenum disulfide bonded to steel by rubbing a mixture of molybdenum disulfide and syrup in intimate contact with clean steel at elevated temperatures proved the most effective. This coating delayed the onset of fretting to 28,000,000 cycles in contrast to less than 30 cycles for a clean uncoated steel.

Bearing Research

A dependable bearing to carry a radial load at extreme speeds and at high ambient temperatures is desired for use as the turbine-support bearing in aircraft gas turbines where the gravity loads are usually under 1,000 pounds and the DN (diameter in millimeters multiplied by revolutions per minute) values are as high as 1×10^6 . To develop such a bearing it is necessary to know the operating characteristics and limitations of conventional rolling-contact bearings at high speeds and how these characteristics and limitations may be improved and extended by such means as improved lubrication methods and design modifications. A study has been completed utilizing three types of bearings to determine experimentally the operating characteristics of conventional cylindrical roller bearings at high speeds at DN values from 0.3×10^6 to 1.65×10^6 and static radial loads from 7 to 1,613 pounds with circulatory oil feed (Technical Note 2128). The operating temperatures of the bearings were found to differ most appreciably in the low-load high-speed range where the roller-riding cage-type bearing exhibited significantly lower operating temperatures than the one- and two-piece inner-race-riding cage-type bearings. However, the operation of the roller-riding bearings was considerably rougher than that of the inner-race-riding bearings and they showed prohibitive cage and roller wear.

A continuation of the study outlined above was undertaken to compare and to evaluate the effects of oil-

inlet location, jet angle, and jet velocity on outer- and inner-race bearing temperatures for single-jet lubrication over a wide range of variables (Technical Note 2216). The effect of oil flows of 0.6 to 12.9 pounds per minute and oil inlet velocities of 13 to 200 feet per second were studied utilizing a one-piece inner-race-riding brass cage bearing over a load range of 113 to 368 pounds and DN values of 0.3×10^6 to 1.43×10^6 . For the conditions studied, the inner- and outer-race temperatures were found to be at a minimum when the oil was directed at the cage-locating surface perpendicular to the bearing face. A mathematical correlation based on heat transfer considerations was obtained such that for a given operating condition a representative single straight line resulted regardless of whether the bearing speed, oil flow, or jet diameter was varied.

COMPRESSOR AND TURBINE RESEARCH

Compressor Research

Both high-speed and long-range aircraft utilizing gas-turbine power plants require light compact compressors with large air-flow capacities and high pressure ratios and efficiencies. Compressor research, therefore, is being directed toward solving aerodynamic problems of compressing air efficiently in a compressor of minimum frontal area, minimum length, and minimum complexity, so that the unit will be mechanically sturdy and easily manufactured. A reliable engine having comparatively low initial cost can thus be obtained. Compressor research consists of theoretical work on compressor aerodynamics, guide vane studies, cascade investigations, and single-stage and multistage compressor investigations.

The theoretical approach to the aerodynamics of compressors has been concentrated on obtaining a working knowledge of the flow phenomena associated with the compressor and its operating conditions. As an approach to the solution of the three-dimensional flow through compressors, a general through-flow theory corresponding to axially symmetric flow has been developed (Technical Note 2302). The theory is applicable to both *direct* and *inverse* problems and is derived primarily for use in machines having thin blades of high solidity.

In order to approximate the circumferential variation of the flow conditions, which is neglected in the through-flow solution, several different approaches have been used. When the radial component of flow is negligible, the flow follows along cylindrical surfaces and may be analyzed in terms of the equivalent two-dimensional cascade. The method developed for designing cascade blades (Technical Note 2281) with prescribed velocity distribution for subsonic compressible flow based on a linear pressure-volume relation has

been extended, and expressions for estimating the accuracy of solutions have been developed.

For cases where the radial component of velocity is not negligible, a better approximation to the actual flow is obtained by assuming the flow to take place along the surfaces of revolution, as obtained from the axially symmetric solution, and then determining the flow between the blades along these surfaces of revolution. Both the direct and inverse problem for subsonic flow have been analyzed (Technical Note 2407).

A rapid but approximate blade-element-design method (Technical Note 2408) for compressible or incompressible nonviscous flow in high-solidity stators or rotors of axial-, radial-, or mixed-flow compressors has been developed. The method is based on channel-type flow between blade elements on a specified surface of revolution that lies between the hub and shroud and is concentric with the axis of the compressor. The blade element is designed for prescribed velocities along the blade-element profile.

The characteristic equations for the axially symmetric flow in supersonic impellers have been developed and used to investigate flows in several configurations in order to ascertain the effect of variations of the boundary conditions on the internal flow and work input (Technical Note 2388).

A theoretical discussion of the application of blade boundary-layer control to increase the efficiency and the stage pressure ratio and to improve off-design performance of turbomachines is given in Technical Note 2371. Also presented is a method based on potential flow of a compressible fluid for designing suction, or ejection slotted, blades having a prescribed velocity distribution along the blade and in the slot.

The boundary-layer profiles on the casing of an axial-flow compressor were measured behind the guide vanes and behind the rotor. Using these measurements and three-dimensional boundary-layer momentum-integral equations which were developed (Technical Note 2310), a qualitative consideration of boundary-layer behavior on the walls of an axial-flow compressor was made. This consideration shows that the important parameters concerning the secondary flows in the boundary layers are the turning of the flow and the product of the curvature of the streamline outside the boundary layer by the boundary-layer thickness.

Turbine Research

The problems associated with the turbine component of the turbojet engine are similar to those of the compressor when good performance is required for application to transonic and supersonic aircraft. The problems in obtaining light, efficient, and dependable turbine components for driving compressors are in general

the result of compromising the turbine aerodynamics with mechanical considerations to obtain reasonable stresses. The turbine research is therefore being aimed at improving the turbine performance. Turbine cooling is also commanding considerable attention as a means of improving the compromise between the requirements of stress and aerodynamics. Turbine research consists of theoretical turbine aerodynamics in which the theories and tools developed for compressors are readily applicable, cascade investigations, and single-stage and multistage turbine research.

In order to facilitate the determination of the best design compromises in the design of turbines, a method was developed for the computation and graphical presentation of a series of possible turbine designs for any specific application. Design charts are made to aid in the study of the effects of turbine radius ratio and diameter on important design parameters such as Mach number, turning angle, and blade root stress. The method for constructing these charts is presented in Technical Note 2402.

Non-twisted-type rotor blades are desirable where internal passages in the blades are required for turbine cooling. An analytical evaluation has been made of the aerodynamic characteristics of turbines with non-twisted rotor blades by comparison with the corresponding characteristics of free-vortex turbines. The results of this investigation, including working charts for aid in designing non-twisted-rotor-blade turbines, are presented in Technical Note 2365.

Turbine Cooling

The research program for the application of cooling to gas turbines has two objectives. The first is the elimination of critical metals from the turbine rotor of gas-turbine engines so that alloy steels of higher strength and lower critical material content can be used while extending the useful life of turbine blades. The second objective is to provide the means of operating gas turbines at higher gas temperatures to achieve the large potential gains in thrust of the turbojet engine, and the increase in power and the lower specific fuel consumption inherent in the turbine-propeller engine. Past analyses and cascade investigations show that the blade-temperature reduction required to permit substitution of noncritical metals can be achieved with acceptable coolant flow.

Solutions for a system of generalized equations for the laminar boundary layer with heat transfer have been developed for the determination of local heat-transfer coefficients. Numerical solutions have been obtained for low Mach numbers over a wide range of coolant flow, temperature ratio, and pressure gradient with allowance for fluid property variations. Solutions to the equa-

tions for the high Mach number range are now being effected through the use of automatic computing machines (Technical Note 2207).

Analytical methods for computing one-dimensional spanwise or chordwise temperature distributions in liquid-cooled turbine blades or in simplified shapes used to approximate sections of liquid-cooled turbine blades have been summarized (Technical Note 2321).

Blade Vibration and Flutter

An experimental spin rig was used to determine the effect of root design on the damping of loosely mounted blades. The conventional ball-and-dovetail roots were shown to have the same characteristics in that tightening occurred at relatively low values of centrifugal force, thus eliminating the advantages of the loose fit. The fir-tree and the hinge designs, however, had different characteristics, the fir-tree tightening at the relatively high centrifugal loadings and the hinge root remaining loose throughout the speed range investigated.

Methods have been developed for computing the natural modes and frequencies of arbitrarily shaped twisted cantilever beams. Use has been made of the concept of station functions. An analysis is being made by this method to compute the natural modes and frequencies of a group of different compressor and turbine blades. The computed values will be compared with experimental values in order to evaluate the analytical method (Technical Note 2300).

ENGINE PERFORMANCE AND OPERATION

Performance and Operating Characteristics

The performance of turbojet, turbopropeller, and ram-jet engines has been investigated over a range of altitudes and flight Mach numbers. In addition to obtaining altitude performance characteristics, the effects of Reynolds number, burner blow-out limits, altitude starting characteristics, and component performance were studied. As a result of these investigations basic design changes were recommended which result in improved power plant performance for future engines. Various principles of thrust augmentation have been evaluated experimentally under a variety of engine operating conditions.

An analysis was made to obtain an expression for the optimum jet-pressure ratio for any turbine-propeller engine. The results of this analysis, reported in Technical Note 2178, are presented in the form of charts from which the jet-pressure ratio for the division of power giving maximum thrust may be obtained for engines either with or without intercooling, reheat, regeneration, or any combination of these modifications.

Analytical evaluations of different methods of power extraction from an axial-flow-type turbojet engine have

been completed. These results have been presented in terms of generalized parameters that facilitate their application to different engines. The data cover the range of power extractions available from the engines on a range considered ample for all auxiliary-power requirements. The power-extraction methods are compressor-outlet air bleed, shaft-power extraction, turbine-inlet or tail-pipe hot-gas bleed, and the use of a tail-pipe heat exchanger on a turbojet engine as an auxiliary power (or energy) source. The first three parts of this investigation are reported in Technical Notes 2166, 2202, and 2304.

Engine Controls

A variety of engine control loops have been evaluated experimentally to determine effects of interaction and stability on engine operation. Several theoretical studies were conducted to determine optimum control arrangements for various engine types.

An analysis was made of the effect of independent variations in the component efficiency characteristics, flight conditions, and engine size on the time constant and the turbine-inlet-temperature overshoot of a turbojet engine with a centrifugal compressor and a turbine with choked stator. The dynamic factors were calculated from the thermodynamic equations of engine-component performance. This investigation is reported in Technical Note 2182.

The general form of transfer functions for a turbojet engine with tailpipe burning was developed and the relations among the variables in these functions were found from the transfer functions and from engine thermodynamics (Technical Note 2183). By means of these relations, the dynamic characteristics of the engine can be found from steady-state data and one transient relation.

As reported in Technical Note 2378, a rational analytic method for the design of automatic control systems was developed that starts from certain arbitrary criteria on the transient behavior of the system and derives those physically realizable characteristics of the controllers that satisfy the original criteria.

Accurate knowledge of the dynamic response characteristics of turbine-propeller engines and the factors that affect these characteristics are of great importance in the design of quick-acting, stable controls for this type engine. An investigation of the dynamics of a turbine-propeller engine was made at sea level (Technical Note 2184) and in the altitude wind tunnel employing the frequency-response technique for a range of altitudes.

Directing research effort toward the improvement of the turbine-propeller engine requires an appreciation of the relative importance of the various engine-component characteristics. An analysis is being made to

determine the influence of interdependent characteristics, such as component size, efficiency, and flow capacity, on the performance of the turbine-propeller engine. Results are evaluated on an airplane-performance basis so as to reveal the ultimate effects of the variables under investigation.

Thrust Augmentation

A theoretical analysis of thrust augmentation of turbine-propeller engines is in progress. Methods of augmentation considered are tail-pipe burning, compressor-inlet water injection, and a combination of water-injection and tail-pipe burning. Augmented performance with tail-pipe burning has been determined for high subsonic and for supersonic speeds. Calculations are in progress on the augmented performance with water injection over a range of flight conditions from take-off to transonic flight at altitude, and on the performance at high speeds with a combination of water injection and tail-pipe burning.

An analysis is being conducted for the prediction of the jet flows, pumping characteristics, and jet thrust obtainable from conical ejectors in order to determine the rules for the design of such ejectors for maximum effectiveness. A one-dimensional analysis of conical-air-ejector performance was made using an assumed pressure gradient along the conical secondary shroud.

ENGINE MATERIALS RESEARCH

High Temperature Materials

As a part of the search for materials having physical properties suitable for use at higher and higher operating temperatures, considerable effort is being expended in trying to improve the physical properties of the current materials. Factors which influence the high temperature strength of alloys are melting practice, forging, or casting procedures, and the heat treatments selected. To gain a better understanding how heat treatment affects the structures of alloys and the resulting physical properties, studies have been conducted of the fundamental factors which control the properties of austenitic alloys having exceptionally high creep and rupture strengths in the temperature range of 1,200° F. and 1,500° F. Such a study has been completed on Inconel X (Technical Note 2385). Correlations of the mechanical properties with structural analyses were made. It appeared from the study that aging resulted in some improvement in rupture strength in the range from 100–1,000 hours rupture time at 1,200° F. This improvement was obtained apparently through increasing the resistance to creep prior to fracture. This is in contrast to results obtained with N-155 wherein the improvement appeared to be through the formation of a grain boundary phase.

As a part of the study of the conservation of strategic materials for aircraft engines, efforts are being directed toward the evaluation of substitute materials of reduced alloy content. Among the materials studied for sheet applications is AISI 310B (Technical Note 2162). One of the draw-backs of this material has been low ductility in the temperature range from 1,200° F. to 1,400° F. The objective of this research was to determine whether service at 1,700° F. to 1,800° F. would cause increased brittleness at 1,200° F. to 1,400° F. with resultant cracking during heating and cooling. Stress rupture tests were made in the 1,200° F. to 1,400° F. range with a few tests at 1,700° F. and 1,800° F. Among the variables considered were heat-to-heat reproducibility, the relative effects of annealing, and hot and cold working as initial treatments. It was found that the elongation at 1,300° F. was increased by prior heating from 1,700° F. to 2,000° F. In addition, it was determined that the cold-rolled stock had the lowest ductility.

Inasmuch as several of the important high-temperature alloys utilize both chromium and cobalt and because a number of the physical properties of an alloy are controlled by diffusion processes within the alloy in the solid state, an investigation was conducted to determine the diffusion coefficients of chromium in the alpha cobalt-chromium solid solutions (Technical Note 2218). The method employed consisted of pressure-welding cobalt and cobalt-chromium bars, annealing these joined bars at constant temperatures and determining the distribution of chromium through the diffusion zones thus formed. It was found that the diffusion coefficients at 1,000° C., 1,150° C., 1,300° C., and 1,360° C. were relatively constant. It was further found that chromium diffusivity from alpha cobalt-chromium alloys into cobalt is greater than chromium diffusivity from high-chromium alpha alloys to low-chromium alpha alloys for all concentration gradients studied.

Studies of the properties of molybdenum at high temperatures have been continued. The effects of swaging, recrystallization, and "test-section" area on the strength properties of sintered wrought molybdenum were determined at temperatures from 1,800° F. to 2,400° F. (Technical Note 2319). The amount of swaging on the specific bar sizes investigated had little effect on the tensile strengths, but increasing amounts of swaging progressively lowered the recrystallization temperature. Increasing the test-section area of a specimen had a negligible effect on the tensile strength. Wrought molybdenum had a 100-hour stress-rupture life of approximately $19,300 \pm 300$ p. s. i. at 1,800° F.

Studies of ceramic coatings for the protection of ceramals and less strategic alloys from high temperature oxidation and corrosion have led to the develop-

ment of a ceramic coating with a high chromium metal content. Evaluations of these coatings on a TiC base ceramal have demonstrated the ability of the coating to protect against oxidation as well as its ability to withstand small elongations and severe thermal shock (Technical Notes 2329 and 2386). It was found that in general the best protection was obtained in oxidation tests at the higher temperatures. Studies of the effects of firing time, firing temperature, and the number of coatings applied indicated that there is an optimum firing time and firing temperature. For the coating studied, two applications proved superior to one.

Studies of the effectiveness of ceramic coatings in preventing high temperature corrosion by lead-bromide vapors indicate that the ceramic coatings appeared to be inert to the PbBr_2 and successfully inhibited corrosion of the alloys studied for a 6-hour test period (Technical Note 2380). The alloys S-816, HS-21, Inconel, 19-9DL, and AISI 347 were tested (*a*) in an uncoated condition, (*b*) in a preoxidized condition, and (*c*) in a coated condition when exposed to the lead-bromide fumes in an air atmosphere at 1,350° F., 1,500° F., and 1,650° F.

As a part of the general program for the evaluation of ceramals, investigations have been completed of the bonding of TiC with Al, Be, Cu, Au, Fe, Pb, Mg, Mn, Pt, Ti, and V (Technical Note 2187). The test procedure consisted of placing powdered metal in a cup-shaped depression formed in a hot-pressed TiC test bar, inserting the specimen in a furnace at temperatures up to 3,650° F. Studies were made of the sectioned specimens to determine what kind of bonding, if any, took place. Of the elements studied, only nickel, cobalt, chromium, and silicon bonded with titanium carbide. There was some indication of a limited solubility of titanium carbide in nickel and cobalt.

A continuation of the study outlined above was conducted, utilizing zirconium carbide and columbium to determine the bonding mechanism (Technical Note 2198). The results indicated that the mechanism is one in which columbium atoms diffuse into the zirconium-carbide lattice, displace zirconium atoms, and form zirconium metal and a completely soluble columbium carbide. This results in a homogenous solid solution of the zirconium-carbide matrix and the columbium carbide. The size and the distribution of the metal phase was controlled by sintering time and temperature. In general, the specimen with a fine dispersion of metal had the highest strength.

Stresses Research

The failure of turbine and compressor blades due to vibrations has led to an increased interest in the de-

termination of the natural modes and frequencies. Assuming a compressor or turbine blade acts as a cantilever beam, a method has been developed for calculating the coupled modes (Report 1005). The method is based on the concept of Station Functions and permits the calculation of the modes and the frequencies of nonuniform cantilever beams vibrating in torsion, bending, and coupled bending-torsion motion. Results of the application of this method show that the effect of coupling between bending and torsion is to reduce the first natural frequency to a value below that which it would have if there were no coupling.

In the design of a turbine rotor it is desirable to know the detailed stress and strain distributions in the strain-hardening range and the amount of increase in load that can be sustained between the onset of yielding and failure. A simple method of solving the plane-stress problems with axial symmetry, employing the finite strain concept in the strain-hardening range, and based on the deformation theory of Hencky and Nadai, has been derived for the condition that the directions and ratios of the principal stresses remain constant during loading (Technical Note 2217). The results indicated that the ratios of the principal stresses remain essentially constant during loading and, therefore, the deformation theory is applicable to this type of problem. In general, it may be said that the deformation that can be accepted by the member before failure depends primarily on the maximum octahedral shear strain of the material.

In the design of high-stressed machine parts, a knowledge of the stress and strain concentration due to a hole and also of the distributions of stresses and strains in the strain-hardening range is desirable. As a continuation of the work reported above, a linearized solution has been obtained for the problem of plastic deformation of a thin plate with a circular hole in the strain-hardening range (Technical Note 2301). This solution is based on the deformation theory of plasticity for finite strains. The results indicate that the data obtained by the linearized method compare closely with those obtained without linearization. In addition, it was found that the solution for an ideally plastic material with the infinitesimal strain concept gives good approximate values of strains but not of stresses.

A further study of the distribution of stresses and strains in the strain-hardening range has led to a partly linearized solution of the plastic deformation of a rotating disk considering finite strains (Technical Note 2367). The results indicate that the variation of a parameter, which is determined from the octahedral shear stress-strain curve of the material, can be used as a gen-

eral criterion of the applicability of the deformation theory. In addition, it appeared that the rotating speed of a disk for a given maximum strain of the disk can be determined directly from the true tensile stress-strain curve of the material.

A continuation of the investigation reported in Report 1005 has been completed to determine the effect of twist on vibrations of cantilever beams (Technical Note 2300). It is shown that for a beam with a ratio of bending stiffness in the two principal directions equal to 144, the effect of coupling due to twisting is to raise the value of the first natural frequency by a very small amount, to decrease steadily the second frequency, and to lower the third frequency considerably.

A significant question to be considered in the specification of chemical composition and mechanical and thermal treatment of a rotor disk is the compromise between ductility and tensile strength. An investigation was conducted to determine the strength-reducing effects of several types of irregularities, various ductilities, and an optimum compromise between ductility and the tensile strength in the presence of such defects (Technical Note 2397). The strength of disks containing irregularities increased with increasing tensile strength independently of ductility at ductilities in excess of 14.9 percent elongation. The best compromise between ductility and tensile strength in material containing shrink porosity occurred at 6.8 percent elongation.

The application of X-ray diffraction techniques to a study of stress analysis indicates that the back reflection techniques will yield a reasonable strain accuracy under favorable conditions. Because the conventional experimental methods reduce the precision in determining interatomic spacing and restrict the analysis to those materials which yield a reasonably sharp diffraction pattern, a new technique and camera have been devised (Technical Note 2224). A calibration of the camera, using a gold powder standard having a reported atomic spacing of 0.91008A, yielded an accuracy of

atomic spacing of approximately $\pm 4 \times 10^{-5}$ A. A comparison of the new technique with the results obtained from the conventional equipment and techniques indicated that a more precise and detailed analysis of atomic strain could be obtained.

ROCKET RESEARCH

The major problems of rocket research are to select fuel and oxidant combinations that give large thrust per unit weight flow and volume flow and still have properties that permit their handling and use, to prevent failure of the engine from high temperatures attained, to achieve efficient combustion in the smallest possible unit, and to evaluate the optimum application of rocket propulsion.

Rocket Propellants

Investigations of rocket-propellant performance are usually preceded by theoretical analyses of the performance of various fuel-oxidant combinations. These analyses are used as a basis for selecting the propellants worthy of experimental evaluation. Compilation of the thermodynamic functions to be used in these analyses has been continued.

An analysis was made to show the relative importance of specific impulse and propellant density on missile performance. The analysis compares propellant combinations having different specific impulses and densities by determining the least gross weight of a missile to accomplish a given mission.

Rocket Combustion

A basic study of the hydraulic characteristics of injection systems was started as an aid in establishing the relation between injector method and combustion characteristics. Initial studies of two impinging jets of water revealed that the spray disintegrates into groups of drops which for the conditions existing in a rocket correspond to frequencies observed in combustion fluctuations. These results are reported in Technical Note 2349.

AIRCRAFT CONSTRUCTION

The NACA is continuing its efforts to enlarge the scope and the amount of its research on airframe construction problems. The need for such an increase in effort has been previously pointed out and the manner in which it is to be accomplished is under study.

Programs during the past year have included extensive laboratory and flight research and the continued collection of statistical data on gust loads encountered in regular airline operation. All airframe construction problems have been complicated by the increasing altitude and speeds of flight and these two factors can be

found at the root of most new structural design problems.

As in the past, a considerable amount of the NACA research on structural materials and structures was performed under contract at universities and other non-profit scientific organizations.

In accordance with the policy of holding technical conferences with representatives of the military services and the aircraft industry, a conference on aircraft loads and structures was held at the Langley Laboratory in the spring of 1951.

A description of the Committee's recent unclassified research on airframe construction is given in the following pages and is divided in four sections: Aircraft loads, structures, vibration and flutter, and aircraft structural materials.

AIRCRAFT STRUCTURES

Stress Distribution

Experimental investigations have shown that the stresses and distortions arising at the wing-fuselage juncture of swept wings are appreciably different from those occurring in straight wings. Some theoretical work showing the effects of sweep-back on the deflection of box beams under bending and torsion loadings had been published, but there was a need for an analysis giving the stresses at the triangular root section of a swept box beam. Accordingly, a method presented in Technical Note 2232 was developed for analyzing the triangular portion of the box beam and for establishing continuity between this section and the carry-through section, as well as the outboard portions of the box beam. The results obtained by this method were compared with previously published test data. The agreement was found to be fair, with the principal discrepancy being due to the fact that the method is based on a very simple type of idealized structure which prevents the appearance of shear lag in the results. An extension of the basic approach was therefore made in order that it might include the effects of shear lag.

Exact solutions for the stresses and deformations in wings subjected to torsion are not easily obtained. Oregon State College has therefore developed an approximate method of solving for the angle of twist, longitudinal stresses, and shear stresses in torsion boxes of rectangular, elliptical and airfoil cross sections. The results of these theoretical studies indicate trends for consideration in design.

For proper design of cut-outs that occur in stiffened-shell structures, a detailed knowledge of the redistribution of stresses around the cut-outs is necessary. An approximate theory had been developed for the analysis of stresses in torsion boxes containing large cut-outs which is adequate for the design of all components of such structures except the cut-out cover. This theory was extended in Technical Note 2290 to permit a more detailed calculation of the stresses in the cover. Numerical results were compared with experimental data and also with the results of a solution made by a more elaborate numerical procedure. The agreement was found to be satisfactory in all cases except those with very large cut-outs and flexible bulkheads.

For analysis of thin solid wings of small aspect ratio, such as might be used in supersonic airplanes and missiles, beam theory is no longer adequate. Wings of this

type are more nearly plates than beams and can be analyzed by plate theory. However, solutions to the partial-differential equations of plate theory are not readily obtained, especially for plates of arbitrary shape and loading. A method is presented in Technical Note 2369 for obtaining ordinary differential equations to replace the partial-differential equations. This simplified plate theory has been applied to specific problems involving static deflection, vibration, and buckling of cantilever plates.

One proposed method for increasing the storage space inside a wing is to replace the ribs with a number of vertical posts connecting the compression and tension covers of the wing box beam. A theoretical study of an idealized post-box configuration had indicated that the compression cover of a box beam could be stabilized by posts with an attendant weight saving. In order to check the validity of the theory developed, a beam was tested and the results reported in Technical Note 2414. The experimental buckling load was in good agreement with theory, but appreciable distortion of the beam cross section occurred before the buckling load was reached. It was concluded that a proper combination of posts and ribs may make a design that would be satisfactory with regard to both deformation and strength.

The skin on the upper surface of a wing is subjected to compression by the bending of the wing, and in most cases the addition of stiffening elements to the skin is required to enable the compression load to be carried. Direct-reading design charts have been prepared for 75S-T6 aluminum alloy flat compression panels having longitudinal extruded Z-section stiffeners. These charts, which are presented in Technical Note 2435, cover a wide range of propositions and make possible the direct determination of panel dimensions required to carry a given intensity of loading with a given skin thickness and effective length of panel. They also make possible the determination of the panel proportions having minimum weight and meeting the design conditions.

A type of sandwich plate widely used in airplane construction consists of a corrugated metal sheet riveted between two metal face sheets. In order to apply existing sandwich-plate theories to the analysis of the corrugated-core sandwich plate, a knowledge of certain elastic constants which describe the distortions of the sandwich plate under simple loadings is required. Formulas for evaluating these elastic constants for the corrugated-core type of sandwich have therefore been derived and presented in Technical Note 2289. Suggestions have also been made as to the method of extending existing sandwich-plate theory to make it strictly applicable to the unsymmetrical type of corrugated-core sandwich.

Pressurized cabins of high-altitude airplanes present many stress analysis problems unusual to the aircraft field. These problems have been reviewed by Stanford University and a report containing a summary of the available information on these problems has been prepared.

The ultimate load-carrying capacity of stiffened-shell structures which are subjected to combined loads is a subject on which little information is available. In order to investigate one phase of this problem, a series of five large stiffened circular cylinders was tested to failure under various combinations of torsion and compression. An interaction curve for the strength of stringers that fail by local crippling was determined, and data were obtained on stringer stresses for stiffened cylinders under combined loads. The test results and a method for estimating stiffener stresses are presented in Technical Note 2188.

Stability

In 1947 Shanley showed that it was possible for a straight column in the plastic stress range to start to bend at a load given by the Euler formula with the tangent modulus of elasticity substituted for Young's modulus of elasticity. He also pointed out the existence of a maximum column load which was greater than the tangent-modulus load. In order to determine the amount by which the maximum load could exceed the tangent-modulus buckling load, a study of column behavior in the plastic stress range was undertaken, the results of which are reported in Technical Note 2267. This study confirmed the existence of the tangent-modulus buckling load, and showed by a rigorous load-deflection analysis the relation of the maximum load to the stress-strain curve of the material.

A thin-walled fuselage may buckle either by deformation of the entire column (column buckling) or by deflection of its component webs and flanges (local buckling). Methods are available for the determination of the buckling load for each mode of failure, and it is common practice to assume that a column will fail at the lower of the two loads in a mode corresponding to this load. In reality, however, there is an interaction of these two modes of buckling so that the actual buckling load is smaller than that which is ordinarily used. An investigation has therefore been conducted by Cornell University for the purpose of determining the interaction effect between column and local buckling. The results of this study indicate that this effect is negligible for box sections and for common sizes of I, H, and channel sections but may be significant for sections possessing torsional instability, such as T and angle shapes.

A method has been developed by the National Bureau of Standards for computing the compressive load for lateral elastic instability of hat-section stringers and is presented in Technical Note 2272. Applying the method to a range of shapes and lengths of hat-section stringers shows that such stringers are unlikely to fail by lateral instability.

The use of swept wings and tail plan forms with ribs placed parallel to the flight path results in sheet panels that are parallelogram-shaped. Few data exist on the stability of such panels under the loadings that arise due to wing and tail bending. Accordingly, in Technical Note 2392 charts have been prepared giving theoretical compressive-buckling-stress coefficients for continuous flat sheet divided by nondeflecting supports into parallelogram-shaped panels. Over a wide range of panel aspect ratio, such panels are decidedly more stable than equivalent rectangular panels of the same area.

Thermal Effects

The determination of the structural effects of nonuniform temperature distributions, such as might be produced by aerodynamic heating, is rapidly becoming a problem of interest to aircraft designers because non-uniform temperature distributions have important and complex effects on the stresses and distortions of the structure. The calculation of the stresses due to non-uniform temperature distributions has been treated by several investigators, since the problem has long been of concern to power-plant designers; however, methods that would be directly applicable to the thermoelastic analysis of aircraft structures are not yet available. Two preliminary studies have therefore been completed on this subject. The first, reported in Technical Note 2240, considers the two effects of temperature changes on aircraft structures: The introduction of thermal stresses and distortions as a result of restrained thermal expansion, and the change in behavior of the structure resulting from the variation of elastic properties of materials with temperature. These effects have been illustrated by sample analyses of the stress and distortion distributions of simple box beams and by calculation of the stresses in a typical wing section. The analytical methods of the first study provide a relatively simple means of approximating the effects of temperature changes; however, they often yield inaccurate values for the secondary stresses in complicated structures, and in such cases some numerical approach is desirable. The second study, reported in Technical Note 2241, extends a previously published numerical method of stress analysis to include the effects of a nonuniform distribution of temperature. An illustrative analysis using this method was made of a two-cell box beam under the

combined action of vertical loads and a nonuniform temperature distribution.

Syracuse University has conducted an experimental investigation of the temperature and stress gradients resulting from the application of heat to the skin of a number of skin and spar cap combinations. The 75S-T6 aluminum alloy specimens with a range of skin thicknesses were heated at various rates to provide a better understanding of heat flow through high-speed aircraft wings.

Fatigue

An investigation is being conducted on the fatigue strength of full-scale airplane structures. The results, to date, indicate a surprisingly small amount of spread in the fatigue life even though all the fatigue cracks do not originate at the same point. Effective stress-concentration factors have been computed and compared with results from tests of small laboratory specimens. The importance of fatigue crack length on crack growth is pointed out in these tests. In connection with this work the structural damping of a typical airplane wing has been determined. These measurements were carried out by the shock-excitation method, with the resultant frequency of vibration being that of the wing fundamental bending frequency. The results are in agreement with those of other experimenters who have measured structural damping of smaller wing specimens. They indicate that the damping increases with amplitude of vibration.

AIRCRAFT LOADS

Steady Flight Loads

A simplified lifting-surface theory has been applied to the problem of evaluating span loading due to flap deflection for arbitrary wing planforms (Technical Note 2278). A procedure was developed from which the effects of flap deflection on span loading and associated aerodynamic characteristics can easily be computed for any wing that is symmetrical about the root chord and that has a straight quarter-chord line over the wing semispan. The effects of compressibility and spanwise variation of section lift-curve slope are taken into account by the procedure. The load distribution and lift due to flap deflection were prepared in chart form for a broad range of wing planforms for the case of straight tapered wings and a comparison between experimental values of flap effectiveness and values obtained from these charts show good agreement between theory and experiment.

Maneuvering Loads

As airplanes increase in size and weight, experimental data must be obtained to evaluate current maneuvering tail-load design requirements and to assist in extrapolation to the larger airplanes. The need for data arises from the variations in the response of the airplane as size increases, and also because a pilot's mental attitude and his control actions will vary according to the size and type of airplane. In view of the gaps in existing data a joint project for flight testing the Lockheed Constitution (design gross weight 184,000 pounds) was conducted by the Navy Department, Bureau of Aeronautics, and the NACA.

These tests, reported in Technical Note 2490, indicated that the analytical process of estimating the maneuvering tail loads for a large airplane need be little different from that for small airplanes. The flexibility of the tail had a minor effect on the estimated tail load and the resulting response of the airplane. Because of the relatively slow response of the airplane, the pilot was forced to anticipate the airplane response in applying control forces; for this reason the pilots often unknowingly obtained undesirably high load factors. The pilots were unaware of the critical tail loads arising from abrupt restoration of the control to neutral during a pull-up or sideslip. Pilots also expressed the opinion that the rolling pull-out maneuver felt similar to maneuvers required to recover from disturbances to flight in rough air.

Gust Loads

The dynamic behavior of an airplane wing during flight through rough air was investigated by flight tests on a twin-engine transport airplane. Results from flights made in clear-air turbulence were compared with results from slow pull-ups made in smooth air used as a quasi-static reference condition (Technical Note 2424).

As an extension of previous investigations of the effect of sweep on gust loads, tests were made in the Langley gust tunnel on a 60° swept-back-wing model to determine the effect of a large angle of sweep on gust loads. The results indicate that a simplified method of analysis, using a slope of the lift curve derived by the cosine law and strip theory to estimate the penetration effect is applicable to the prediction of gust loads on wings swept as much as 60°. These results as well as a summary curve representing the results of investigations with wing models having from 45° sweep-forward to 60° sweep-back are presented in Technical Note 2204.

An instrument to indicate atmospheric turbulence has been constructed and subjected to laboratory and flight tests. The design of the instrument was based on previous findings that the rapid fluctuations of the air speed in gusty air constituted a measure of atmospheric turbulence. The instrument consists essentially of a vented air-speed diaphragm in a sealed case with the lag characteristics of the vent chosen so that the diaphragm responds to the rapid changes in dynamic pressure in gusty air but remains insensitive to gradual changes resulting from normal air-speed changes. The results of flight and laboratory tests indicate that the principle of design was a practicable one, but further design refinement would be necessary if the instrument were to be used in routine airplane operations.

The effect of atmospheric turbulence on the loads encountered by aircraft in operational flight has been studied for some time by analyzing records secured with the NACA V-G (airspeed-acceleration) recorder. The instrument originally employed was troublesome to adjust and was limited in frequency response. An improved recorder has been developed which employs a viscous-damped accelerometer. Improved frequency response of the accelerometer has resulted and the necessity for adjusting damping in the field has been eliminated. The motion of the air-speed element has been made approximately linear with air speed; in addition, the element has been temperature-compensated. The new NACA oil-damped V-G recorder and its performance characteristics are described in Technical Note 2194, and the results of tests which demonstrate improvements to the older design are presented.

The NACA VGH recorder described in Technical Note 2265 is a flight instrument designed to collect gust-loads data on transport aircraft with the accuracy required for research purposes. Air speed, normal acceleration, and altitude are recorded on photographic paper as a function of time and in the usual applications 100 hours of continuous recording time is possible. A small acceleration-sensing unit used with the recorder can be mounted independently of the recorder. Although built principally for collecting statistical data on gusts encountered in scheduled airline operations, the instrument records data in a manner which permits many studies pertaining to airplane operations which have air speed, normal acceleration, and altitude as parameters.

Landing Loads

With the advent of thin wings for high-speed flight, the increased use of external stores, and the trend toward airplanes of larger size, a knowledge of the behavior of flexible wings during landing becomes increasingly important. An investigation of a model

consisting of a hull in combination with a flexible wing was made in the Langley impact basin, and the data are reported in Technical Note 2343. These data substantiated a theoretical method for considering the effect of structural flexibility on the applied hydrodynamic force.

The development of retractable lifting surfaces for imparting favorable hydrodynamic behavior to streamlined hulls has shown a trend toward the use of comparatively flat surfaces which blend with the bottom of a fuselage. Data on the impact loads and energy absorption of heavily loaded flat surfaces when landed at various trims and flight-path angles are reported in Technical Note 2330.

The validity of the reduced-mass method of representing wing-lift effects in free-fall drop tests of landing gears has been investigated and the results are reported in Technical Note 2400. The behavior of a small landing gear in the reduced-mass drop tests was compared with results obtained in a drop test where wing lift forces simulating airborne impact were mechanically applied to the test specimen during impact, and with results obtained in free-fall drop tests with full weight. Values of landing-gear load factor and ratio of shock-strut energy to impact energy obtained from reduced-mass drop tests were in fairly good agreement with the results obtained from simulated airborne impacts. The values of impact period and shock-strut effectiveness were generally lower in the reduced-mass drop tests than in the simulated airborne impacts, while strut stroke and mass travel were generally greater in the reduced-mass drop tests than in the simulated airborne impacts. The free-fall drop tests with full weight produced excessive values of load factor, impact period, strut stroke, mass travel, and impact energy, but values of strut effectiveness were in fairly good agreement with those obtained in the simulated airborne impacts.

VIBRATION AND FLUTTER

Increased effort is being expended upon flutter studies for transonic and supersonic speeds. Unusual configurations are also being investigated in order to keep pace with design trends for these speeds.

Unsteady Lift Theories

Calculations have been made of the forces on aerodynamic bodies in unsteady motion based upon the classical equations governing acoustic disturbances. These calculations have been greatly expedited by applying techniques which were developed in recent investigations of steady state supersonic theory. The build-up of lift and pitching moments on slender, triangular wings and wing sections undergoing sinking

and pitching motions were calculated for subsonic, sonic, and supersonic speeds. These results have been reported in Technical Notes 2256, 2387, and 2403. These transient responses provide the necessary information for the prediction of responses to oscillatory motions of arbitrary frequency and are therefore applicable to problems in airplane dynamics and flutter calculations.

Iterative Solution of Flutter

Existing methods of flutter analysis include the representative-section method, generalized coordinate methods, matrix methods, and operational methods. Wielandt has suggested an iterative transformation procedure which is well suited to the flutter problem and similar characteristic-value problems. Because both the original and the translated work of Wielandt are difficult to follow, an explanation of the iterative-transformation procedure is given in Technical Note 2346 and the application of the procedure to ordinary natural vibration problems and to flexure-torsion flutter problems is shown in numerical examples. It appears from this work that the method is of practical usefulness. Comparisons of computed results with experimental results and with results obtained with other methods of analysis have also been made.

Effect of Coupling Between Modes

In an analysis of flutter involving coupled vibrations, questions arise concerning the accuracy of using uncoupled modes or coupled modes, as the latter greatly complicate the analysis. An analysis of the Raleigh type based on coupled modal functions, was made for a wing with simulated engines, or tip tanks, representing a wing with high mass coupling. The wing considered was uniform, unswept, and high aspect ratio, and was mounted as a cantilever. The results of this analysis were compared with those of an analysis based on uncoupled modes as well as with experimental results. For the configurations studied, agreement with experimental data was obtained for both methods of analysis; therefore, the more complicated coupled-mode analysis may be unnecessary (Technical Note 2375).

Single Degree of Freedom Flutter

Beside the usual types of flutter involving coupled modes, the theoretical existence of a single-degree-of-freedom flutter has been indicated and is of interest in dynamic stability. Therefore it was deemed advisable to study the effects of some parameters affecting this single-degree-of-freedom oscillation. One such analytical study concerned the effect of Mach number and structural damping on single-degree-of-freedom pitching oscillations of a wing. Some experimental results

were compared with theory and good agreement was found for certain ranges of an inertia parameter (Technical Note 2396).

Sound

Propeller noise has been a problem even at subsonic tip speeds; hence the proposed use of propellers operating at supersonic tip speeds has caused some concern because of the severity of the associated noise problem. Very little information is available which would allow a prediction of noise levels. Therefore sound measurements have been made for a two-blade propeller with a tip Mach number of 1.30. Sound spectrums were obtained at both subsonic and supersonic tip speeds, and the measured data were compared with calculations by the Gutin theory.

AIRCRAFT STRUCTURAL MATERIALS

Fatigue of Metals

The project on fatigue at Battelle Memorial Institute mentioned in previous annual reports has continued, and significant progress has been made in fulfilling the purpose of the program, which is to provide information sufficiently comprehensive to permit its application to design and to the estimation of fatigue damage. The materials being investigated in this program are 24S-T3 and 75S-T6 aluminum alloys and SAE 4130 steel. Results previously reported on unnotched specimens are contained in Technical Note 2324. Fatigue data on notched specimens over a range of stress concentration factors of 1.5 to 5.0 are the subject of several other reports. Those on stress concentration factors of 2.0 and 4.0 are in Technical Note 2389, and those on stress concentration factors of 5.0 are given in Technical Note 2390. Data have also been obtained on specimens having a stress concentration factor of 1.5. This range of stress concentrations is considered to be that of most importance in aircraft from the fatigue viewpoint.

In the investigation of the statistical nature of fatigue at Carnegie Institute of Technology during the past year, the statistics of the fatigue fracture curves and endurance limits were determined for SAE 1050 steel, annealed Armco iron, and SAE 4340 steel in the quenched and tempered and quenched and spheroidized conditions. The effects of metallurgical factors such as composition, heat treatment, and cleanliness on fatigue behavior were shown by a statistical analysis of the experimental results. From this work it has been concluded that inclusions play the dominant role in the fatigue behavior of these materials. In addition, some other aspects of the fatigue problem were studied, among which were the dependence of statistical variations in fatigue life on stress level in the fracture range,

the statistics of the location of crack initiation, size effect, and understressing effects.

Axial fatigue tests were conducted at the National Bureau of Standards on flat sheet specimens of bare and alclad 24S-T3 aluminum alloy to determine the effect of frequency of loading on the fatigue strengths of these materials. The results of this investigation are contained in Technical Note 2231 and show that the fatigue strengths of the materials were slightly less when tested at 12 cycles per minute than when tested at 1,000 cycles per minute.

Another aspect of the fatigue problem was investigated at the Pennsylvania State College. The purpose of this project was to determine the influence of biaxial tensile stresses on the fatigue strength of 14S-T4 aluminum alloy when subjected to various ratios of biaxial stresses. These biaxial fatigue stresses were produced by applying simultaneously a pulsating internal pressure and fluctuating axial tensile load to a thin-walled tubular specimen. Fatigue strengths and S-N diagrams were obtained up to about 10,000,000 cycles for four principal stress ratios. The test results do not agree with any particular theory of failure but are sufficiently close to the maximum stress theory to permit its use in design.

Plasticity

In the 1950 annual report reference was made to an investigation at the Pennsylvania State College on the plastic biaxial stress-strain relations. The results of biaxial tensile stress tests on 75S-T6 material are published in Technical Note 2425, and the results of similar tests on 14S-T4 aluminum alloy were obtained during the past year. The main purpose of this investigation was to determine the validity of the plasticity theories and the correctness of the various assumptions made in these theories. To accomplish this purpose and to supplement the biaxial tensile test results the investigation was extended to include tests in which specimens were subjected to biaxial tension and compression. In these tests both constant and variable stress ratios were used. Although the data obtained do not agree with any of the current plasticity theories, it was found that the biaxial yield strength conforms most closely with the distortion energy theory.

For mathematical simplicity most plasticity theories assume solids to be isotropic and plastically incompressible. These assumptions fix the value of Poisson's ratio in the plastic range at 0.5. Physical considerations, however, make it apparent that the transition from the elastic to the plastic value of Poisson's ratio is gradual. An investigation of the variation in Poisson's ratio in the yield region of the stress-strain curve was completed by New York University during the past

year. It is in this region that the transition from the elastic to the plastic value is most pronounced. This transition was studied experimentally by a systematic system of tests on 14S-T6, 24S-T4, and 75S-T6 aluminum alloys under simple tensile and compressive stresses along three orthogonal axes. The data obtained on Poisson's ratio in the yield region as well as values of the plastic dilatation for strain deviations up to 0.6 percent are given in Technical Note 2561.

Creep

In the design of structures required to operate at elevated temperatures, knowledge of the characteristics of materials at these temperatures is essential. One of the phenomena associated with elevated temperatures is that of creep, the time-dependent distortion of metals under stress. It is felt that a better understanding of creep phenomena will allow the more efficient use of materials in design. The experimental data available, however, are in general not sufficiently detailed nor do they cover a wide enough range in conditions to be effective for use in design, and although several theories have been advanced to account for creep behavior, these theories are not complete enough to be of much help. A study of the fundamental mechanism of the creep of metals has been initiated, therefore, at the Battelle Memorial Institute. Before proceeding with the experimental work, Battelle conducted a survey of the existing knowledge in the field. This survey, released as Technical Note 2516, treats the creep of both single-crystal and polycrystalline metals. The modes of deformation in short-time, low-temperature tests are considered, as well as the various theories which purport to explain the behavior of metals during creep. Battelle is now obtaining experimental data on the creep of 2S aluminum alloy over a wide temperature range and comparing these data with available theories. Should the data conform with none of these, efforts will be made to develop an appropriate theory to try to account for all the observed phenomena.

Stress Corrosion

The Armour Research Foundation in its investigation of stress corrosion has developed equipment which will permit observation and recording of the relative potentials of various regions near the surface of a metallic specimen during corrosion. By means of this equipment it is possible to locate the anodic and cathodic areas on a corroding surface and identify such areas with the corresponding metallurgical feature. Technical Note 2523 presents a description of this equipment and describes the techniques developed for the interpretation of the data obtained. The equipment is now being used to investigate the stress corrosion

mechanism of a high-purity binary alloy, aluminum—4-percent copper.

Corrosion

The investigation of the corrosive properties of metals jointly sponsored by the NACA, Bureau of Aeronautics, and the Air Matériel Command has continued at the National Bureau of Standards. The purpose of this investigation is to determine the rate of corrosion of materials used in aircraft when exposed to marine atmosphere and tidewater. During the past year data were obtained from exposure tests on galvanized steel stitched-aluminum alloys. These are reported in Technical Note 2299. The effect of hot dimpling on the corrosion of aluminum alloys 75S-T6 and alclad 75S-T6 was evaluated and results were also obtained from corrosion tests of magnesium alloy ZK60.

Hydrogen Embrittlement

A fundamental study was conducted at the Battelle Memorial Institute on the mechanism by which hydrogen enters metals, particularly aircraft steels, causing hydrogen embrittlement during chemical or electrochemical action. Several known methods of controlling the inlet and exit of hydrogen in steel were correlated with the known chemical behavior of atomic and molecular hydrogen. By means of this correlation it was found possible to select suitable reagents which significantly decreased hydrogen permeability and embrittlement of steel during cathodic pickling operations in dilute sulfuric acid. The same data show that the diffusion of hydrogen in steel and the freedom of exit of hydrogen are important in determining the extent of embrittlement and also that these phenomena are chemical in nature rather than mechanical.

Adhesives

In the manufacture of aircraft the bonding of sandwich panels, consisting of aluminum alloys bonded to various core materials, and the bonding of aluminum to itself by means of adhesives offers several important advantages over other methods of fastening, and there is considerable interest at the present time in such processes. There is a need, however, for an adhesive adequate for use at elevated temperatures. This led to the investigation at Forest Products Laboratory on the effects of temperature on the bond strength of joints fabricated with adhesives. The evaluation of the performance of commercially available metal bonding adhesives in the temperature range of -70° to 600° F. has been completed. The evaluation of the relative merits of the materials is based upon the data obtained from tensile

tests of joints both when tested immediately upon reaching the test temperature and after several days' exposure at the test temperature.

Plastics

The investigation of the loss of strength of plastic glazing as a result of crazing has continued at the National Bureau of Standards. Since plastic glazing is used in the windows and canopies of airplanes, this property is of considerable interest to the aircraft industry. The meager information on the subject was expanded during the past year by two reports from the National Bureau of Standards. In one of these, Technical Note 2444, the loss in strength of several grades of polymethyl methacrylate due to stress solvent crazing is discussed. In this investigation tensile specimens were artificially crazed by applying benzene to the central portion of the specimen while it was under stress. Among the factors studied were the sheet-to-sheet variability of crazing specimens and the relative effect of a few large crazing cracks compared with more numerous finer cracks. Applying benzene to the specimens caused a loss of strength of approximately 30 percent in all of the materials.

An investigation was completed at the National Bureau of Standards on the strength of heat-resistant laminates up to 375° C. The flexural properties of samples of glass fabric laminates such as are used in radomes were determined for several loading cycles at elevated temperatures. The laminates tested were bonded with various resins, including unsaturated polyester, acrylic, silicone, phenolic, and melamine types. Tests of a silicone resin laminate showed it to be superior to the other laminates in retention of flexural properties at temperatures of 250° C. or higher (Technical Note 2266). At temperatures of 300° to 325° C. this laminate retained at least 30 percent of its initial flexural strength and over 50 percent of its initial modulus of elasticity.

Materials Evaluation

The light weight, high-strength, corrosion-resistant, and favorable elevated-temperature properties of titanium have aroused interest in the possibility of using this material for aircraft structural applications. In order to indicate the potentialities of this material, an evaluation of titanium including comparisons with several other aircraft materials has been made for typical structural applications. The procedure developed for this purpose provides a general method for determining the structural efficiency of a material for a particular structural application (Technical Note 2269).

OPERATING PROBLEMS

Investigations have been continued of the meteorological conditions adverse to the performance and safety of flight, means of accurately measuring air speed and static pressure at transonic and supersonic speeds, principles of design of aircraft systems for coping with natural icing conditions, and methods of improving aircraft safety. Research on atmospheric turbulence, aircraft ditching, and air speed measurement have been conducted by the Langley Aeronautical Laboratory, while studies of natural icing conditions, aircraft ice-protection systems, and aircraft crash fires have been conducted by the Lewis Flight Propulsion Laboratory. The Ames Aeronautical Laboratory has also done limited work in the field of aircraft icing. The work of the NACA laboratories has been supplemented by research conducted by several universities under contract to the NACA.

The practice of holding technical conferences with industry and military representatives was extended to the field of operating problems. A conference on some problems of aircraft operation was held at the Lewis Flight Propulsion Laboratory in the fall of 1950. The Committee on Operating Problems is responsible for the guidance of the operating problems research program. It is aided in specialized aspects of this program by its subcommittees, the Subcommittee on Meteorological Problems, the Subcommittee on Icing Problems, and the Subcommittee on Aircraft Fire Prevention.

AIRCRAFT OPERATION

Air Speed and Altitude Measurement

A systematic investigation of the static-pressure errors ahead of wings and fuselage noses of two low-wing airplanes was conducted in flight (Technical Note 2311). The variation of the static-pressure error with position of the static-pressure tube, located at several points from 0.25 to 2.0 chord lengths ahead of the wing tip and 0.5 to 1.5 fuselage diameters ahead of the nose, was determined over a speed range from the stall up to a maximum of 265 miles per hour. At low lift coefficients, the error decreased with increasing lengths ahead of the wing or fuselage, with variation in error over the lift-coefficient range being approximately the same for the $1\frac{1}{2}$ -diameter fuselage-nose installation and the 1-chord wing-tip installation.

For present-day high-performance airplanes having the capabilities of maneuvering to high angles of attack at supersonic speeds, the need has developed for rigid air-speed tubes which will measure total and static pressures correctly under these conditions. As a means of determining the optimum design of total-pressure

tubes, a series of wind-tunnel tests has been conducted to determine the effect of inclination of the air stream on various types of total-pressure tubes over a wide range of angle of attack through the subsonic and supersonic speed ranges. Preliminary tests on 39 tubes at subsonic speeds are reported in Technical Note 2331. Subsequent tests of 20 of these tubes at supersonic speeds are reported in Technical Note 2261. The results of the tests showed that the tube which remained insensitive over the greatest range of angle of attack, both at subsonic and supersonic speeds, was a shielded total-pressure tube designed for end mounting on a horizontal boom. The range of angle of attack over which this tube remained insensitive (to within 1 percent of the impact pressure) was $\pm 41.5^\circ$ at subsonic speeds and $\pm 37^\circ$ at supersonic speeds. From the results of the tests of the other tubes, the effects of such design factors as external shape, internal shape, and configuration of total-pressure entry were evaluated, and the effect of Mach number on the performance of the various tubes was determined. Studies were also conducted of effects of position and airplane configuration on the measurement of air speed and Mach number in the transonic speed range. The applicability of using pressures on a cone as a measure of angle of attack at transonic speeds was also investigated.

Ditching

The investigation of the ditching characteristics of civil transport-type aircraft was completed with the studies of the behavior of the Convair-Liner. The recommended ditching procedures follow those for other transport types, touchdown being made at fairly high angle of attack with flaps down and landing gear up. The behavior depends upon the manner in which the flaps fail, the maximum deceleration being somewhat greater if the flaps rotate to neutral rather than being carried away.

AERONAUTICAL METEOROLOGY

Prediction of Low-Level Clear-Air Turbulence

Preliminary investigation of the meteorological variables associated with turbulence in clear air within the earth's friction layer led to the development of a simple empirical relation for estimating the intensity of the turbulence. The correlation of the observed gust experience of an airplane with various combinations of meteorological variables showed that a simple product form of the intensity of solar radiation and the average wind shear layer below the first discontinuity in temperature lapse rate gave very good results for condi-

tions similar to those of the tests. This relation accounts for seasonal variations in turbulence intensity but, because of its simplicity, cannot discriminate between differences in turbulence intensity resulting from variations in flight altitude or diurnal variations in turbulence. The relationship has been established only for the limited conditions of terrain and meteorological situations during the flights in the vicinity of Wilmington, Ohio. Significant differences in these conditions will alter the relative importance of the meteorological variables considered.

Radar Detection of Thunderstorm Turbulence

Evaluation of the uses of airborne radar for detection of turbulent areas in thunderstorms was conducted by the Navy with the assistance of the Langley Laboratory staff. The presentation of areas of light rainfall and heavy rainfall on the radar PPI scope allowed preliminary correlation of the gust experience of an airplane with the indicated rainfall gradient. The limited results so far obtained indicated that possibilities of reducing the number and severity of the gusts likely to be encountered in a thunderstorm were good if the areas of high rainfall rate gradient were avoided.

Surface Wind Instruments

A wind-tunnel calibration of instruments for determining wind velocity and direction was conducted for the Signal Corps, United States Army. A three-cup anemometer was calibrated for measuring wind velocities up to 200 miles per hour. Two pressure-type combined wind-velocity and wind-direction indicators were also tested. One with four equally spaced orifices on the perimeter of a circular disk was tested up to 100 miles per hour, and another consisting of a pitot-static head mounted on a pivoted weather vane was tested up to 250 miles per hour.

AIRCRAFT ICING

Research is continuing at the Lewis Flight Propulsion Laboratory and the Ames Aeronautical Laboratory in an effort to establish the meteorological conditions that make up the icing cloud so that this knowledge may be applied toward the efficient design of aircraft ice-protection systems.

Characteristics of the Icing Cloud

The meteorological aspects of the icing cloud are being studied extensively in flight and laboratory investigations to determine what values of meteorological factors exist in the atmosphere and how these data can best be utilized to design efficient types of ice-protec-

tion systems for the various aircraft components. Tentative recommended values of meteorological factors to be considered in the design of aircraft ice-protection systems previously published (Technical Note 1855) have been supplemented with data collected by the NACA and other agencies during the 1948-49 and 1949-50 winter seasons and have been analyzed to present a method for the selection of design criteria. The data are summarized to give frequency of occurrence of icing conditions according to liquid-water content and drop size and further to indicate that statistical relations do exist between liquid-water content, mean effective droplet diameter, temperature, and pressure altitudes. A considerable amount of additional data is needed before a purely statistical analysis can be attempted; however, this accomplishment can be made possible only if the efforts to design suitable meteorological instruments are successful.

The Lewis Laboratory has developed and reported on a reliable pressure-type icing-rate meter that will automatically record icing rate, airspeed, altitude, and time in supercooled clouds. Evaluation tests on research and commercial aircraft indicate that the use of this instrument to collect a large amount of data for a statistical analysis is practical. The operation of the instrument is based on the creation of a differential pressure between an ice-free total-pressure system and a total-pressure system in which small total-pressure holes vented to static pressure are allowed to plug with ice accretion. At a fixed value of ice accretion, the differential pressure operates an electrical heater that de-ices the total-pressure holes. The resulting cyclic process varies with the intensity of the icing and serves as a measure of the icing rate. The simplicity of this operating principle permits automatic operation upon encountering an icing condition and relative freedom from maintenance and operating problems. The complete unit weighs only 18 pounds. Visual indications of the icing intensity are made available to the pilot by periodic flashing of a light on the instrument panel.

Another instrument previously developed as a cloud detector has been further investigated to provide a simple means for measuring liquid-water content in above- and below-freezing clouds. The instrument consists of a small cylindrical element so operated at high surface temperatures that the impingement of cloud droplets creates a significant drop in surface temperature. Preliminary calibrations of this instrument have indicated that improvements are expected to make it a reliable instrument for recording the important meteorological factor of liquid-water content.

Liquid-water content, droplet size, and temperature data measured in predominantly stratiform clouds during the last two icing seasons have been presented in

Technical Note 2306. The average liquid-water content of a cloud layer, as measured by the multicylinder technique, seldom exceeded two-thirds of that which could be released by adiabatic lifting. The horizontal and vertical extent of icing conditions and the relation of the existence of supercooled clouds to cyclonic areas and precipitation regions are indicated.

The Lewis Laboratory is continuing to make progress toward understanding of the fundamental processes involved in the formation of the icing cloud and in methods for its prediction. Part of this study has been a continuation of the investigation of spontaneous freezing temperatures of supercooled water droplets of the size found in the atmosphere. A statistical explanation of the previously reported investigation of spontaneous freezing temperatures of water droplets (Technical Note 2142) has been published in Technical Note 2234. The statistical theory is based on the presence of an assumed crystallization nuclei distribution suspended in the water and results indicate that small droplets may be supercooled to lower temperatures than the large droplets. The probable distribution curves of spon-

aneous freezing temperatures for water droplets of various sizes are given and compared with the experimental results.

Propeller Ice Protection

The Ames Laboratory has completed analytical and experimental investigations of the effect of ice formation on propeller performance (Technical Note 2212). The experimental measurements were made during flight in natural icing conditions, whereas the analysis consisted of an investigation of changes in blade section aerodynamic characteristics caused by ice formation and the resulting propeller efficiency changes. The results indicated that efficiency losses can generally be expected to be less than 10 percent with maximum losses as high as 20 percent to be expected only rarely. The effects of ice accretion on airfoil section characteristics at subcritical speeds, the effect of kinetic heating on the radial extent of ice formation, and the influence of the efficiency loss on the pilot's adjustment of engine and propeller controls are also discussed.

- No.
973. Flight Investigation of the Effect of Various Vertical-Tail Modifications on the Directional Stability and Control Characteristics of a Propeller-Driven Fighter Airplane. By Harold I. Johnson.
974. The Supersonic Axial-Flow Compressor. By Arthur Kantrowitz.
975. Small Bending and Stretching of Sandwich-Type Shells. By Eric Reissner.
976. Linear Theory of Boundary Effects in Open Wind Tunnels with Finite Jet Lengths. By S. Katzoff, Clifford S. Gardner, Leo Diesendruck, and Bertram J. Eisenstadt.
977. Frequency Response of Linear Systems from Transient Data. By Melvin E. Laverne and Aaron S. Boksenbom.
978. Method of Designing Cascade Blades with Prescribed Velocity Distributions in Compressible Potential Flows. By George R. Costello.
979. On Stability of Free Laminar Boundary Layer between Parallel Streams. By Martin Lessen.
980. General Algebraic Method Applied to Control Analysis of Complex Engine Types. By Aaron S. Boksenbom and Richard Hood.
981. Theoretical Analysis of Various Thrust-Augmentation Cycles for Turbojet Engines. By Bruce T. Lundin.
982. Icing-Protection Requirements for Reciprocating-Engine Induction Systems. By Willard D. Coles, Vern G. Rollin, and Donald R. Mulholland.
983. Line-Vortex Theory for Calculation of Supersonic Downwash. By Harold Mirels and Rudolph C. Haefeli.
984. Method for Determining the Frequency-Response Characteristics of an Element or System from the System Transient Output Response to a Known Input Function. By Howard J. Curfman, Jr. and Robert A. Gardiner.
985. A Radar Method of Calibrating Airspeed Installations on Airplanes in Maneuvers at High Altitudes and at Transonic and Supersonic Speeds. By John A. Zalovecik.
986. The Reversibility Theorem for Thin Airfoils in Subsonic and Supersonic Flow. By Clinton E. Brown.
987. Equilibrium Operating Performance of Axial-Flow Turbojet Engines by Means of Idealized Analysis. By John C. Sanders and Edward C. Chapin.
988. Comparative Drag Measurements at Transonic Speeds of Rectangular and Sweptback NACA 65-009 Airfoils Mounted on a Freely Falling Body. By Charles W. Mathews and Jim Rogers Thompson.
989. Critical Stress of Ring-Stiffened Cylinders in Torsion. By Manuel Stein, J. Lyell Sanders, Jr., and Harold Crate.
990. An Analysis of Supersonic Aerodynamic Heating with Continuous Fuel Injection. By E. B. Klunker and H. Reese Ivey.
991. The Application of the Statistical Theory of Extreme Values to Gust-Load Problems. By Harry Press.
992. Theoretical Comparison of Several Methods of Thrust Augmentation for Turbojet Engines. By Eldon W. Hall and E. Clinton Wilcox.
993. An Introduction to the Physical Aspects of Helicopter Stability. By Alfred Gessow and Kenneth B. Amer.
994. Analysis of Spanwise Temperature Distribution in Three Types of Air-Cooled Turbine Blade. By John N. B. Livingood and W. Byron Brown.
995. Blockage Corrections for Three-Dimensional-Flow Closed-Throat Wind Tunnels, with Consideration of the Effect of Compressibility. By John G. Herriot.
- No.
996. Free-Space Oscillating Pressures near the Tips of Rotating Propellers. By Harvey H. Hubbard and Arthur A. Regier.
997. Summary of Information Relating to Gust Loads on Airplanes. By Philip Donely.
998. Further Experiments on the Flow and Heat Transfer in a Heated Turbulent Air Jet. By Stanley Corrsin and Mahinder S. Uberoi.
999. Investigation of the NACA 4-(3)(08)-03 and NACA 4-(3)(08)-045 Two-Blade Propellers at Forward Mach Numbers to 0.725 to Determine the Effects of Compressibility and Solidity on Performance. By John Stack, Eugene C. Draley, James B. Delano, and Lewis Feldman.
1000. Calculation of the Aerodynamic Loading of Swept and Unswept Flexible Wings of Arbitrary Stiffness. By Franklin W. Diederich.
1001. Fundamental Effects of Aging on Creep Properties of Solution-Treated Low-Carbon N-155 Alloy. By D. N. Frey, J. W. Freeman, and A. E. White.
1002. On the Theory of Oscillating Airfoils of Finite Span in Subsonic Compressible Flow. By Eric Reissner.
1005. Analytical Determination of Coupled Bending-Torsion Vibrations of Cantilever Beams by Means of Station Functions. By Alexander Mendelson and Selwyn Gendler.

TECHNICAL NOTES ¹

- No.
2092. Approximate Aerodynamic Influence Coefficients for Wings of Arbitrary Plan Form in Subsonic Flow. By Franklin W. Diederich.
2111. A Study of Water Pressure Distributions during Landings with Special Reference to a Prismatic Model Having a Heavy Beam Loading and 30° Angle of Dead Rise. By Robert F. Smiley.
2117. Design and Applications of Hot-Wire Anemometers for Steady-State Measurements at Transonic and Supersonic Airspeeds. By Herman H. Lowell.
2120. Development and Preliminary Investigation of a Method of Obtaining Hypersonic Aerodynamic Data by Firing Models through Highly Cooled Gases. By Harold V. Soule and Alexander P. Sabol.
2123. Investigation of Turbulent Flow in a Two-Dimensional Channel. By John Laufer.
2124. Spectrums and Diffusion in a Round Turbulent Jet. By Stanley Corrsin and Mahinder S. Uberoi.
2126. Improvements in Heat Transfer for Anti-Icing of Gas-Heated Airfoils with Internal Fins and Partitions. By Vernon H. Gray.
2128. Investigation of 75-Millimeter-Bore Cylindrical Roller Bearings at High Speeds. I—Initial Studies. By E. Fred Macks and Zolton N. Nemeth.
2129. Method of Calculating the Lateral Motions of Aircraft Based on the Laplace Transform. By Harry E. Murray and Frederick C. Grant.
2130. Calculation of Transonic Flows Past Thin Airfoils by an Integral Method. By William Perl.
2131. Boundary-Layer Transition on a Cooled 20° Cone at Mach Numbers of 1.5 and 2.0. By Richard Scherrer.
2132. The Calculation of Modes and Frequencies of a Modified Structure from Those of the Unmodified Structure. By Edwin T. Kruszewski and John C. Houbolt.

¹ The missing numbers in the series of Technical Notes were released before or after the period covered by this report.

- No. 2133. Investigation of Separation of the Turbulent Boundary Layer. By G. B. Schubauer and P. S. Klebanoff.
2134. Comparison of Model and Full-Scale Spin Test Results for 60 Airplane Designs. By Theodore Berman.
2135. The Calculation of Downwash Behind Wings of Arbitrary Plan Form at Supersonic Speeds. By John C. Martin.
2136. Theory of Helicopter Damping in Pitch or Roll and a Comparison with Flight Measurements. By Kenneth B. Amer.
2137. An Analysis of Base Pressure at Supersonic Velocities and Comparison with Experiment. By Dean R. Chapman.
2138. Analytical and Experimental Investigation of Adiabatic Turbulent Flow in Smooth Tubes. By Robert G. Deissler.
2139. Effect of Variation in Rivet Diameter and Pitch on the Average Stress at Maximum Load for 24S-T3 and 75S-T6 Aluminum-Alloy, Flat, Z-Stiffened Panels that Fail by Local Instability. By Norris F. Dow and William A. Hickman.
2140. Theoretical Antisymmetric Span Loading for Wings of Arbitrary Plan Form at Subsonic Speeds. By John DeYoung.
2141. Charts for Estimating Downwash Behind Rectangular, Trapezoidal, and Triangular Wings at Supersonic Speeds. By Rudolph C. Haefeli, Harold Mirels, and John L. Cummings.
2142. Photomicrographic Investigation of Spontaneous Freezing Temperatures of Supercooled Water Droplets. By Robert G. Dorsch and Paul T. Hacker.
2143. Analysis of the Effects of Boundary-Layer Control on the Power-Off Landing Performance Characteristics of a Liaison Type of Airplane. By Elmer A. Horton, Laurence K. Loftin, Jr., and Stanley F. Racisz.
2144. Effect of Chemical Reactivity of Lubricant Additives on Friction and Surface Welding at High Sliding Velocities. By Edmond E. Bisson, Max A. Swikert, and Robert L. Johnson.
2145. Lift-Cancellation Technique in Linearized Supersonic-Wing Theory. By Harold Mirels.
2146. On the Effect of Subsonic Trailing Edges on Damping in Roll and Pitch of Thin Sweptback Wings in a Supersonic Stream. By Herbert S. Ribner.
2147. Some Conical and Quasi-Conical Flows in Linearized Supersonic-Wing Theory. By Herbert S. Ribner.
2148. Laminar-Boundary-Layer Heat-Transfer Characteristics of a Body of Revolution with a Pressure Gradient at Supersonic Speeds. By William R. Wimbrow and Richard Scherrer.
2149. Investigation of Boundary-Layer Control to Improve the Lift and Drag Characteristics of the NACA 65-415 Airfoil Section with Double Slotted and Plain Flaps. By Elmer A. Horton, Stanley F. Racisz, and Nicholas J. Paradiso.
2150. Flight Investigation of the Effect of Transient Wing Response on Measured Accelerations of a Modern Transport Airplane in Rough Air. By C. C. Shuffeberger and Harry C. Mickleboro.
2151. Estimation of the Damping in Roll of Supersonic-Leading-Edge Wing-Body Combinations. By Warren A. Tucker and Robert O. Piland.
2152. Shear Stress Distribution Along Glue Line Between Skin and Cap-Strip of an Aircraft Wing. By C. B. Norris and L. A. Ringelstetter.
- No. 2153. The Stability of the Compression Cover of Box Beams Stiffened by Posts. By Paul Seide and Paul F. Barrett.
2154. An Analysis of the Autorotative Performance of a Helicopter Powered by Rotor-Tip Jet Units. By Alfred Gessow.
2155. Calculated Engine Performance and Airplane Range for Variety of Turbine-Propeller Engines. By Tibor F. Nagey and Cecil G. Martin.
2156. Theoretical Calculations of the Lateral Force and Yawing Moment Due to Rolling at Supersonic Speeds for Sweptback Tapered Wings with Streamwise Tips. Supersonic Leading Edges. By Sidney M. Harmon and John C. Martin.
2157. Static and Impact Strengths of Riveted and Spot-Welded Beams of Alclad 14S-T6, Alclad 75S-T6, and Various Tempers of Alclad 24S Aluminum Alloy. By H. E. Grieshaber.
2158. A General Integral Form of the Boundary-Layer Equation for Incompressible Flow with an Application to the Calculation of the Separation Point of Turbulent Boundary Layers. By Neal Tetervin and Chia Chiao Lin.
2159. On the Particular Integrals of the Prandtl-Busemann Iteration Equations for the Flow of a Compressible Fluid. By Carl Kaplan.
2160. Measurements of Section Characteristics of a 45° Swept Wing Spanning a Rectangular Low-Speed Wind Tunnel as Affected by the Tunnel Walls. By Robert E. Dannenberg.
2161. Tables of Thermodynamic Functions for Analysis of Aircraft-Propulsion Systems. By Vearl N. Huff and Sanford Gordon.
2162. Investigation of Properties of AISI-Type 310B Alloy Sheet at High Temperatures. By E. E. Reynolds, J. W. Freeman, and A. E. White.
2163. Critical Stress of Plate Columns. By John C. Houbolt and Elbridge Z. Stowell.
2164. Axial-Momentum Theory for Propellers in Compressible Flow. By Arthur W. Vogeley.
2165. Method of Analysis for Compressible Flow through Mixed Flow Centrifugal Impellers of Arbitrary Design. By Joseph T. Hamrick, Ambrose Ginsburg, and Walter M. Osborn.
2166. Effect of Heat and Power Extraction on Turbojet-Engine Performance. II—Effect of Compressor-Outlet Air Bleed for Specific Modes of Engine Operation. By Frank E. Rom and Stanley L. Koutz.
2167. Sonic-Flow-Orifice Temperature Probe for High-Gas-Temperature Measurements. By Perry L. Blackshear, Jr.
2168. Experimental Investigation of the Effect of Vertical-Tail Size and Length and of Fuselage Shape and Length on the Static Lateral Stability Characteristics of a Model with 45° Sweptback Wing and Tail Surfaces. By M. J. Queijo and Walter D. Wolhart.
2169. Wind-Tunnel Investigation at Low Speed of a 45° Sweptback Untapered Semispan Wing of Aspect Ratio 1.59 Equipped with Various 25-Percent-Chord Plain Flaps. By Harold S. Johnson and John R. Hagerman.
2170. Effect of Initial Mixture Temperature on Flame Speeds and Blow-Off Limits of Propane—Air Flames. By Gordon L. Dugger.
2171. Investigation of a Two-Step Nozzle in the Langley 11-Inch Hypersonic Tunnel. By Charles H. McLellan, Thomas W. Williams, and Mitchel H. Bertram.

- No.
2172. Low-Speed Investigation of the Stalling of a Thin, Faired, Double-Wedge Airfoil with Nose Flap. By Leonard M. Rose and John M. Altman.
2173. Density Fields around a Sphere at Mach Numbers 1.30 and 1.62. By Paul B. Gooderum and George P. Wood.
2174. Comparison of the Experimental Pressure Distribution on an NACA 0012 Profile at High Speeds with that Calculated by the Relaxation Method. By James L. Amick.
2175. Effect of an Unswept Wing on the Contribution of Unswept-Tail Configurations to the Low-Speed Static and Rolling-Stability Derivatives of a Midwing Airplane Model. By William Letko and Donald R. Riley.
2176. An Analysis of the Normal Accelerations and Airspeeds of a Four-Engine Airplane Type in Postwar Commercial Transport Operations on Trans-Pacific and Caribbean-South American Routes. By Thomas L. Coleman and Paul W. J. Schumacher.
2177. Low-Speed Characteristics of Four Cambered, 10-Percent-Thick NACA Airfoil Sections. By George B. McCullough and William M. Haire.
2178. Method for Determining Optimum Division of Power between Jet and Propeller for Maximum Thrust Power of a Turbine-Propeller Engine. By Arthur M. Trout and Eldon W. Hall.
2179. Turning-Angle Design Rules for Constant Thickness Circular-Arc Inlet Guide Vanes in Axial Annular Flow. By Seymour Lieblein.
2180. Effectiveness of Molybdenum Disulfide as a Fretting-Corrosion Inhibitor. By Douglas Godfrey and Edmond E. Bisson.
2181. The Aerodynamic Forces and Moments on a 1/10-Scale Model of a Fighter Airplane in Spinning Attitudes as Measured on a Rotary Balance in the Langley 20-Foot Free-Spinning Tunnel. By Ralph W. Stone, Jr., Sanger M. Burk, Jr., and William Bihrlé, Jr.
2182. Analysis of Effect of Variations in Primary Variables on Time Constant and Turbine-Inlet-Temperature Overshoot of Turbojet Engine. By Marcus F. Heidmann.
2183. Analysis for Control Application of Dynamic Characteristics of Turbojet Engine with Tail-Pipe Burning. By Melvin S. Feder and Richard Hood.
2184. Investigation of Frequency-Response Characteristics of Engine Speed for a Typical Turbine-Propeller Engine. By Burt L. Taylor III, and Frank L. Oppenheimer.
2185. Analytical Determination of Coupled Bending-Torsion Vibrations of Cantilever Beams by Means of Station Functions. By Alexander Mendelson and Selwyn Gendler.
2186. Method for Determining Pressure Drop of Air Flowing through Constant-Area Passages for Arbitrary Heat-Input Distributions. By Benjamin Pinkel, Robert N. Noyes, and Michael F. Valerino.
2187. Bonding Investigations of Titanium Carbide with Various Elements. By Walter J. Engel.
2188. Experimental Investigation of Stiffened Circular Cylinders Subjected to Combined Torsion and Compression. By James P. Peterson.
2189. The Development and Performance of Two Small Tunnels Capable of Intermittent Operation at Mach Numbers between 0.4 and 4.0. By Walter F. Lindsey and William L. Chew.
2190. The Use of an Uncalibrated Cone for Determination of Flow Angles and Mach Numbers at Supersonic Speeds. By Morton Cooper and Robert A. Webster.
- No.
2191. Theoretical Investigation and Application of Transonic Similarity Law for Two-Dimensional Flow. By W. Perl and Milton M. Klein.
2192. A Survey of the Flow at the Plane of the Propeller of a Twin-Engine Airplane. By John C. Roberts and Paul F. Yaggy.
2193. Effect of Heat-Capacity Lag on a Variety of Turbine-Nozzle Flow Processes. By Robert B. Spooner.
2194. The NACA Oil-Damped V-G Recorder. By Israel Taback.
2195. A Flight Investigation and Analysis of the Lateral-Oscillation Characteristics of an Airplane. By Carl J. Stough and William M. Kauffman.
2196. Effect of Heat-Capacity Lag on the Flow through Oblique Shock Waves. By H. Reese Ivey and Charles W. Cline.
2197. Pressure Distribution and Damping in Steady Pitch at Supersonic Mach Numbers of Flat Swept-Back Wings Having All Edges Subsonic. By Harold J. Walker and Mary B. Ballantyne.
2198. Sintering Mechanism between Zirconium Carbide and Columbium. By H. J. Hamjian and W. G. Lidman.
2199. Wind-Tunnel Investigation at Low Speed of the Lateral Control Characteristics of an Unswept Untapered Semi-span Wing of Aspect Ratio 3.13 Equipped with Various 25-Percent-Chord Plain Ailerons. By Harold S. Johnson and John R. Hagerman.
2200. A Study of Second-Order Supersonic-Flow Theory. By Milton D. Van Dyke.
2201. Measurement of the Moments of Inertia of an Airplane by a Simplified Method. By Howard L. Turner.
2202. Effect of Heat and Power Extraction on Turbojet-Engine Performance. III—Analytical Determination of Effects of Shaft-Power Extraction. By Stanley L. Koutz, Reece V. Hensley, and Frank E. Rom.
2203. Boundary-Layer Measurements in 3.84- by 10-Inch Supersonic Channel. By Paul F. Brinich.
2204. Gust-Tunnel Investigation of a Wing Model with Semi-chord Line Swept Back 60°. By Harold B. Pierce.
2205. Theoretical Supersonic Characteristics of Inboard Trailing-Edge Flaps Having Arbitrary Sweep and Taper. Mach Lines behind Flap Leading and Trailing Edges. By Julian H. Kainer and Jack E. Marte.
2206. Graphical Method for Obtaining Flow Field in Two-Dimensional Supersonic Stream to Which Heat is Added. By I. Irving Pinkel and John S. Serafini.
2207. Analysis of Turbulent Free-Convection Boundary Layer on Flat Plate. By E. R. G. Eckert and Thomas W. Jackson.
2208. Analysis of Shear Strength of Honeycomb Cores for Sandwich Constructions. By Fred Werren and Charles B. Norris.
2209. Free Oscillations of an Atmosphere in Which Temperature Increases Linearly with Height. By C. L. Pekeris.
2210. Impact-Pressure Interpretation in a Rarefied Gas at Supersonic Speeds. By E. D. Kane and G. J. Maslach.
2211. An Approximate Method of Calculating Pressures in the Tip Region of a Rectangular Wing of Circular-Arc Section at Supersonic Speeds. By K. R. Czarnecki and James N. Mueller.
2212. The Effect of Ice Formations on Propeller Performance. By Carr B. Neel, Jr., and Loren G. Bright.
2213. Aerodynamic Coefficients for an Oscillating Airfoil with Hinged Flap, with Tables for a Mach Number of 0.7. By M. J. Turner and S. Rabinowitz.

- No. 2214. Formulas and Tables of Coefficients for Numerical Differentiation with Function Values Given at Unequally Spaced Points and Application to Solution of Partial Differential Equations. By Chung-Hua Wu.
2215. Compressibility Correction for Turning Angles of Axial-Flow Inlet Guide Vanes. By Seymour Lieblein and Donald M. Sandercock.
2216. Investigation of 75-Millimeter-Bore Cylindrical Roller Bearings at High Speeds. II—Lubrication Studies—Effect of Oil-Inlet Location, Angle, and Velocity for Single-Jet Lubrication. By E. Fred Macks and Zolton N. Nemeth.
2217. Analysis of Plane-Stress Problems with Axial Symmetry in Strain-Hardening Range. By M. H. Lee Wu.
2218. Diffusion of Chromium in a Cobalt-Chromium Solid Solutions. By John W. Weeton.
2219. The Dynamic Lateral Control Characteristics of Airplane Models Having Unswept Wings with Round- and Sharp-Leading-Edge Sections. By James L. Hassell and Charles V. Bennett.
2220. A Balsa-Dust Technique for Air-Flow Visualization and Its Application to Flow through Model Helicopter Rotors in Static Thrust. By Marion K. Taylor.
2221. Equations and Charts for the Rapid Estimation of Hinge-Moment and Effectiveness Parameters for Trailing-Edge Controls Having Leading and Trailing Edges Swept Ahead of the Mach Lines. By Kenneth L. Goin.
2222. A Method for the Determination of the Spanwise Load Distribution of a Flexible Swept Wing at Subsonic Speeds. By Richard B. Skoog and Harvey H. Brown.
2223. Investigation of the Flow through a Single-Stage Two-Dimensional Nozzle in the Langley 11-Inch Hypersonic Tunnel. By Charles H. McLellan, Thomas W. Williams, and Ivan E. Beckwith.
2224. Multiple-Film Back-Reflection Camera for Atomic Strain Studies. By Anthony B. Marmo.
2225. Bending and Buckling of Rectangular Sandwich Plates. By N. J. Hoff.
2226. Theoretical Analysis of Oscillations in Hovering of Helicopter Blades with Inclined and Offset Flapping and Lagging Hinge Axes. By M. Morduchow and F. G. Hinchey.
2227. Relation between Inflammables and Ignition Sources in Aircraft Environments. By Wilfred E. Scull.
2228. Effects of Modifications to the Leading-Edge Region on the Stalling Characteristics of the NACA 63-012 Airfoil Section. By John A. Kelly.
2229. The Effect of End Plates on Swept Wings at Low Speed. By John M. Riebe and James M. Watson.
2230. Synthesis and Purification of Alkyldiphenylmethane Hydrocarbons. 1—2-Methyldiphenylmethane, 3-Methyldiphenylmethane 2-Ethyldiphenylmethane, 4-Ethyldiphenylmethane and 4-Isopropyldiphenylmethane. By John H. Lamneck, Jr., and Paul H. Wise.
2231. Comparison of Fatigue Strengths of Bare and Alclad 24S-T3 Aluminum-Alloy Sheet Specimens Tested at 12 and 1,000 Cycles Per Minute. By Frank C. Smith, William C. Brueggeman, and Richard H. Harwell.
2232. Stress and Distortion Analysis of a Swept Box Beam Having Bulkheads Perpendicular to the Spars. By Richard R. Heldenfels, George W. Zender, and Charles Libove.
2233. Some Effects on Nonlinear Variation in the Directional Stability and Damping-in-Yawing Derivatives on the Lateral Stability of an Airplane. By Leonard Sternfield.
- No. 2234. Statistical Explanation of Spontaneous Freezing of Water Droplets. By Joseph Levine.
2235. The Boundary-Layer and Stalling Characteristics of the NACA 64A010 Airfoil Section. By Robert F. Peterson.
2236. Supersonic Flow around Circular Cones at Angles of Attack. By Antonio Ferri.
2237. Correlations of Heat-Transfer Data and of Friction Data for Interrupted Plane Fins Staggered in Successive Rows. By S. V. Manson.
2238. Effects on Longitudinal Stability and Control Characteristics of a B-29 Airplane of Variations in Stick-Force and Control-Rate Characteristics Obtained through Use of a Booster in the Elevator-Control System. By Charles W. Mathews, Donald B. Talmage, and James B. Whitten.
2239. Theoretical Investigation of Transonic Similarity for Bodies of Revolution. By W. Perl and Milton M. Klein.
2240. The Effect of Nonuniform Temperature Distributions on the Stresses and Distortions of Stiffened-Shell Structures. By Richard R. Heldenfels.
2241. A Numerical Method for the Stress Analysis of Stiffened-Shell Structures under Nonuniform Temperature Distributions. By Richard R. Heldenfels.
2242. Analytical Investigation of Turbulent Flow in Smooth Tubes with Heat Transfer with Variable Fluid Properties for Prandtl Number of 1. By Robert G. Deissler.
2243. Effect of Cell Shape on Compressive Strength of Hexagonal Honeycomb Structures. By L. A. Ringelstetter, A. W. Voss, and C. B. Norris.
2244. A Comparison of Theory and Experiment for High-Speed Free-Molecule Flow. By Jackson R. Stalder, Glen Goodwin, and Marcus O. Creager.
2245. Calculation of Compressible Potential Flow Past Slender Bodies of Revolution by an Integral Method. By Milton M. Klein and W. Perl.
2246. Method for Determining Distribution of Luminous Emitters in Cone of Laminar Bunsen Flame. By Thomas P. Clark.
2247. A Comparison of the Lateral Controllability with Flap and Plug Ailerons on a Sweptback-Wing Model Having Full-Span Flaps. By Powell M. Lovell, Jr.
2248. Analysis of the Effects of Design Pressure Ratio per Stage and Off-Design Efficiency on the Operating Range of Multistage Axial-Flow Compressors. By Melvyn Savage and Willard R. Westphal.
2249. The Spanwise Distribution of Lift for Minimum Induced Drag of Wings Having a Given Lift and a Given Bending Moment. By Robert T. Jones.
2250. An Analysis of the Applicability of the Hypersonic Similarity Law to the Study of Flow about Bodies of Revolution at Zero Angle of Attack. By Dorris M. Ehret, Vernon J. Rossow, and Victor I. Stevens.
2251. Effects of Mach Number up to 0.34 and Reynolds Number Up to 8×10^6 on the Maximum Lift Coefficient of a Wing of NACA 66-Series Airfoil Sections. By G. Chester Furlong and James E. Fitzpatrick.
2252. Formulas for Source, Doublet, and Vortex Distributions in Supersonic Wing Theory. By Harvard Lomax, Max. A. Heaslet, and Franklyn B. Fuller.
2253. On a Source-Sink Method for the Solution of the Prandtl-Busemann Iteration Equations in Two-Dimensional Compressible Flow. By Keith C. Harder and E. B. Klunker.
2254. Regenerator-Design Study and Its Application to Turbine-Propeller Engines. By S. V. Manson.

- No. 2255. Two-Dimensional Compressible Flow in Centrifugal Compressors with Logarithmic-Spiral Blades. By Gaylord O. Ellis and John D. Stanitz.
2256. Three-Dimensional, Unsteady-Lift Problems in High-Speed Flight—Basic Concepts. By Harvard Lomax, Max. A. Heaslet, and Franklyn B. Fuller.
2257. Temperature Distribution in Internally Heated Walls of Heat Exchangers Composed of Noncircular Flow Passages. By E. R. G. Eckert and George M. Low.
2258. Synthesis of Cyclopropane Hydrocarbons from Methylcyclopropyl Ketone. I—2-Cyclopropylpropene and 2-Cyclopropylpropane. By Vernon A. Slabey and P. H. Wise.
2259. Synthesis of Cyclopropane Hydrocarbons from Methylcyclopropyl Ketone. II—2-Cyclopropyl-1-Pentene, *cis* and *trans* 2-Cyclopropyl-2-Pentene and 2-Cyclopropylpentane. By Vernon A. Slabey and P. H. Wise.
2260. Synthesis and Purification of Some Alkylbiphenyls and Alkylbicyclohexyls. By Irving A. Goodman and Paul H. Wise.
2261. Wind-Tunnel Investigation of a Number of Total-Pressure Tubes at High Angles of Attack. Supersonic Speeds. By William Gracey, Donald E. Coletti, and Walter R. Russell.
2262. Rolling and Yawing Moments for Swept-Back Wings in Sideslip at Supersonic Speeds. By Seymour Lampert.
2263. The Use of a Luminescent Lacquer for the Visual Indication of Boundary-Layer Transition. By Jackson R. Stalder and Ellis G. Slack.
2264. Airfoil Profiles for Minimum Pressure Drag at Supersonic Velocities—General Analysis with Application to Linearized Supersonic Flow. By Dean R. Chapman.
2265. NACA VGH Recorder. By Norman R. Richardson.
2266. Strength of Heat-Resistant Laminates up to 375° C. By B. M. Axilrod and Martha A. Sherman.
2267. Inelastic Column Behavior. By John E. Duberg and Thomas W. Wilder, III.
2268. Tests of Two-Blade Propellers in the Langley 8-Foot High-Speed Tunnel to Determine the Effect on Propeller Performance of a Modification of Inboard Pitch Distribution. By James B. Delano and Melvin M. Carmel.
2269. A Structural-Efficiency Evaluation of Titanium at Normal and Elevated Temperatures. By George J. Heimerl and Paul F. Barrett.
2270. Theoretical Damping in Roll and Rolling Effectiveness of Slender Cruciform Wings. By Gaynor J. Adams.
2271. Further Study of Metal Transfer between Sliding Surfaces. By J. T. Burwell and C. D. Strang.
2272. Lateral Elastic Instability of Hat-Section Stringers under Compressive Load. By Stanley Goodman.
2273. Similarity Laws for Transonic Flow about Wings of Finite Span. By John R. Spreiter.
2274. Extension of the Theory of Oscillating Airfoils of Finite Span in Subsonic Compressible Flow. By Eric Reissner.
2275. A Survey of Stability Analysis Techniques for Automatically Controlled Aircraft. By Arthur L. Jones and Benjamin R. Briggs.
2276. Static and Fatigue Strengths of High-Strength Aluminum-Alloy Bolted Joints. By E. C. Hartmann, Marshall Holt, and I. D. Eaton.
2277. Effects of Compressibility on the Performance of Two Full-Scale Helicopter Rotors. By Paul J. Carpenter.
- No. 2278. Theoretical Symmetric Span Loading Due to Flap Deflection for Wings of Arbitrary Plan Form at Subsonic Speeds. By John DeYoung.
2279. Three-Dimensional Compressible Laminar Boundary-Layer Flow. By Franklin K. Moore.
2280. A Theoretical Analysis of the Effects of Fuel Motion on Airplane Dynamics. By Albert A. Schy.
2281. Detailed Computational Procedure for Design of Cascade Blades with Prescribed Velocity Distributions in Compressible Potential Flows. By George R. Costello, Robert L. Cummings, and John T. Sinnette, Jr.
2282. An Improved Approximate Method for Calculating Lift Distributions Due to Twist. By James C. Sivells.
2283. Method for Calculating Lift Distributions for Unswept Wings with Flaps or Ailerons by Use of Nonlinear Section Lift Data. By James C. Sivells and Gertrude C. Westrick.
2284. Lift, Pitching Moment, and Span Load Characteristics of Wings at Low Speed as Affected by Variations of Sweep and Aspect Ratio. By Edward J. Hopkins.
2285. Damping in Roll of Cruciform and Some Related Delta Wings at Supersonic Speeds. By Herbert S. Ribner.
2286. Preliminary Investigation of a New Type of Supersonic Inlet. By Antonio Ferri and Louis M. Nucci.
2287. An Investigation of Pure Bending in the Plastic Range When Loads Are Not Parallel to a Principal Plane. By Harry A. Williams.
2288. Estimation of Low-Speed Lift and Hinge-Moment Parameters for Full-Span Trailing-Edge Flaps on Lifting Surfaces with and without Sweepback. By Jules B. Dods, Jr.
2289. Elastic Constants for Corrugated-Core Sandwich Plates. By Charles Libove and Ralph E. Hubka.
2290. A Method for Calculating Stresses in Torsion-Box Covers with Cutouts. By Richard Rosecrans.
2291. Influence of Wall Boundary Layer upon the Performance of an Axial-Flow Fan Rotor. By Emanuel Boxer.
2292. Experimental Investigation of the Effects of Support Interference on the Drag of Bodies of Revolution at a Mach Number of 1.5. By Edward W. Perkins.
2293. The Physical Properties of Active Nitrogen in Low-Density Flow. By James M. Benson.
2294. Lift and Pitching Derivatives of Thin Sweptback Tapered Wings with Streamwise Tips and Subsonic Leading Edges at Supersonic Speeds. By Frank S. Malvestuto, Jr., and Dorothy M. Hoover.
2295. Chordwise and Compressibility Corrections to Slender-Wing Theory. By Harvard Lomax and Loma Sluder.
2296. Turbulent Boundary-Layer Temperature Recovery Factors in Two-Dimensional Supersonic Flow. By Maurice Tucker and Stephen H. Maslen.
2297. Effect of an Increase in Angle of Dead Rise on the Hydrodynamic Characteristics of a High-Length-Beam-Ratio Hull. By Walter E. Whitaker, Jr., and Paul W. Bryce, Jr.
2298. A Modification to Thin-Airfoil-Section Theory, Applicable to Arbitrary Airfoil Sections, to Account for the Effects of Thickness on the Lift Distribution. By David Graham.
2299. Exposure Tests of Galvanized-Steel-Stitched Aluminum Alloys. By Fred M. Reinhart.
2300. Analytical and Experimental Investigation of Effect of Twist on Vibrations of Cantilever Beams. By Alexander Mendelson and Selwyn Gendler.

- No.
2301. Linearized Solution and General Plastic Behavior of Thin Plate with Circular Hole in Strain-Hardening Range. By M. H. Lee Wu.
2302. A General Through-Flow Theory of Fluid Flow with Subsonic or Supersonic Velocity in Turbomachines of Arbitrary Hub and Casing Shapes. By Chung-Hua Wu.
2303. Correspondence Flows for Wings in Linearized Potential Fields at Subsonic and Supersonic Speeds. By Sidney M. Harmon.
2304. Effect of Heat and Power Extraction on Turbojet-Engine Performance. IV—Analytical Determination of Effects of Hot-Gas Bleed. By Stanley L. Koutz.
2305. An Analytical and Experimental Investigation of the Skin Friction of the Turbulent Boundary Layer on a Flat Plate at Supersonic Speeds. By Morris W. Rubesin, Randall C. Maydew, and Steven A. Varga.
2306. Meteorological Analysis of Icing Conditions Encountered in Low-Altitude Stratiform Clouds. By Dwight B. Kline and Joseph A. Walker.
2307. A Theoretical Method of Determining the Control Gear- ing and Time Lag Necessary for a Specified Damping of an Aircraft Equipped with a Constant-Time-Lag Au- topilot. By Ordway B. Gates, Jr., and Albert A. Schy.
2308. Vibratory Stresses in Propellers Operating in the Flow Field of a Wing-Nacelle-Fuselage Combination. By Vernon L. Rogallo, John C. Roberts, and Merritt R. Oldaker.
2309. Charts for Estimation of Longitudinal-Stability Deriva- tives for a Helicopter Rotor in Forward Flight. By Kenneth B. Amer and F. B. Gustafson.
2310. Generalization of Boundary-Layer Momentum-Integral Equations to Three-Dimensional Flows Including Those of Rotating System. By Artur Mager.
2311. Flight Investigation of the Variation of Static-Pressure Error of a Static-Pressure Tube with Distance Ahead of a Wing and a Fuselage. By William Gracey and El- wood F. Scheithauer.
2312. Bearing Strengths of Some Aluminum-Alloy Permanent- Mold Castings. By E. M. Finley.
2313. The Effects of Mass Distribution on the Low-Speed Dy- namic Lateral Stability and Control Characteristics of a Model with a 45° Sweptback Wing. By Donald E. Hewes.
2314. Effect of Quadratic Terms in Differential Equations of Atmospheric Oscillations. By C. L. Pekeris.
2315. Supersonic Lift and Pitching Moment of Thin Swept- back Tapered Wings Produced by Constant Vertical Ac- celeration. Subsonic Leading Edges and Supersonic Trailing Edges. By Frank S. Malvestuto, Jr., and Doro- thy M. Hoover.
2316. Wind-Tunnel Investigation at Low Speed of Lateral Con- trol Characteristics of an Untapered 45° Sweptback Semispan Wing of Aspect Ratio 1.59 Equipped with Various 25-Percent-Chord Plain Ailerons. By Harold S. Johnson and John R. Hagerman.
2317. Applications of Von Kármán's Integral Method in Super- sonic Wing Theory. By Chieh-Chien Chang.
2318. Full-Scale-Tunnel Investigation of the Static-Thrust Per- formance of a Coaxial Helicopter Rotor. By Robert D. Harrington.
2319. Some Properties of High-Purity Sintered Wrought Molyb- denum Metal at Temperatures up to 2,400° F. By R. A. Long, K. C. Dike, and H. R. Bear.
- No.
2320. Effects of Some Solution Treatments Followed by an Ag- ing Treatment on the Life of Small Cast Gas-Turbine Blades of a Cobalt-Chromium-Base Alloy. I—Effect of Solution-Treating Temperature. By C. Yaker and C. A. Hoffman.
2321. Analysis of Temperature Distribution in Liquid-Cooled Turbine Blades. By John N. B. Livingood and W. Byron Brown.
2322. Creep of Lead at Various Temperatures. By Peter W. Neurath and J. S. Koehler.
2324. Fatigue Strengths of Aircraft Materials. Axial-Load Fatigue Tests on Unnotched Sheet Specimens of 24S-T3 and 75S-T6 Aluminum Alloys and of SAE 4130 Steel. By H. J. Grover, S. M. Bishop, and L. R. Jackson.
2325. Development of Magnesium-Cerium Forged Alloys for Elevated-Temperature Service. By K. Grube, R. Kaiser, L. W. Eastwood, C. M. Schwartz, and H. C. Cross.
2326. Two-Dimensional Subsonic Compressible Flows Past Arbi- trary Bodies by the Variational Method. By Chi-Teh Wang.
2327. Fatigue Testing Machine for Applying a Sequence of Loads of Two Amplitudes. By Frank C. Smith, Darnley M. Howard, Ira Smith, and Richard Harwell.
2328. Method for Determining Pressure Drop of Monatomic Gases Flowing in Turbulent Motion through Constant- Area Passages with Simultaneous Friction and Heat Addition. By M. F. Valerino and R. B. Doyle.
2329. High-Temperature Protection of a Titanium-Carbide Cer- amal with a Ceramic-Metal Coating Having a High Chromium Content. By Dwight G. Moore, Stanley G. Benner, and William N. Harrison.
2330. Water-Landing Investigation of a Model Having Heavy Beam Loadings and 0° Angle of Dead Rise. By A. Ethelda McArver.
2331. Wind-Tunnel Investigation of a Number of Total-Pressure Tubes at High Angles of Attack. Subsonic Speeds. By William Gracey, William Letko, and Walter R. Russell.
2332. Analysis of the Effects of Wing Interference on the Tail Contributions to the Rolling Derivatives. By William H. Michael, Jr.
2333. Transient Aerodynamic Behavior of an Airfoil Due to Different Arbitrary Modes of Nonstationary Motions in a Supersonic Flow. By Chieh-Chien Chang.
2334. On Reflection of Shock Waves from Boundary Layers. By H. W. Liepmann, A. Roshko, and S. Dhawan.
2335. A Plan-Form Parameter for Correlating Certain Aerody- namic Characteristics of Swept Wings. By Franklin W. Diederich.
2336. Some Theoretical Characteristics of Trapezoidal Wings in Supersonic Flow and a Comparison of Several Wing- Flap Combinations. By Robert O. Piland.
2337. Approximate Calculation of Turbulent Boundary-Layer Development in Compressible Flow. By Maurice Tucker.
2338. Experimental Investigation of Localized Regions of Lam- inar-Boundary-Layer Separation. By William J. Bursnall and Laurence K. Loftin, Jr.
2339. Transonic Flow Past a Wedge Profile with Detached Bow Wave—General Analytical Method and Final Calculated Results. By Walter G. Vincenti and Cleo B. Wagoner.
2340. A Survey of Methods for Determining Stability Param- eters of an Airplane from Dynamic Flight Measure- ments. By Harry Greenberg.

- No.
2341. A Least Squares Curve Fitting Method with Applications to the Calculation of Stability Coefficients from Transient-Response Data. By Marvin Shinbrot.
2342. Evaluation of Packed Distillation Columns. I—Atmospheric Pressure. By Thaine W. Reynolds and George H. Sugimura.
2343. Comparison of Theoretical and Experimental Response of a Single-Mode Elastic System in Hydrodynamic Impact. By Robert W. Miller and Kenneth F. Merten.
2344. Method for Calculating Downwash Field Due to Lifting Surfaces at Subsonic and Supersonic Speeds. By Sidney M. Harmon.
2345. The Effect of an Arbitrary Surface-Temperature Variation along a Flat Plate on the Convective Heat Transfer in an Incompressible Turbulent Boundary Layer. By Morris W. Rubesin.
2346. An Iterative Transformation Procedure for Numerical Solution of Flutter and Similar Characteristic-Value Problems. By Myron L. Gossard.
2347. Effect of Aspect Ratio and Sweepback on the Low-Speed Lateral Control Characteristics of Untapered Low-Aspect-Ratio Wings Equipped with Retractable Ailerons. By Jack Fischel and John R. Hagerman.
2348. Effect of Aspect Ratio on the Low-Speed Lateral Control Characteristics of Unswept Untapered Low-Aspect-Ratio Wings. By Rodger L. Naeseth and William M. O'Hare.
2349. Fluctuations in a Spray Formed by Two Impinging Jets. By Marcus F. Heidmann and Jack C. Humphrey.
2350. On the Second-Order Tunnel-Wall-Constriction Corrections in Two-Dimensional Compressible Flow. By E. B. Klunker and Keith C. Harder.
2351. An Experimental Investigation of the Effect of Surface Heating on Boundary-Layer Transition on a Flat Plate in Supersonic Flow. By Robert W. Higgins and Constantine C. Pappas.
2352. Spin-Tunnel Investigation of the Effects of Mass and Dimensional Variations on the Spinning Characteristics of a Low-Wing Single-Vertical-Tail Model Typical of Personal-Owner Airplanes. By Walter J. Klinar and Jack H. Wilson.
2353. Charts and Tables for Use in Calculations of Downwash of Wings of Arbitrary Plan Form. By Franklin W. Diederich.
2354. A Numerical Approach to the Instability Problem of Monocoque Cylinders. By Bruno A. Boley, Joseph Kempner, and J. Mayers.
2355. Achromatization of Debye-Scherrer Lines. By Hans Ekstein and Stanley Siegel.
2356. Two-Dimensional Transonic Flow Past Airfoils. By Yung-Huai Kuo.
2357. Method for Calculation of Ram-Jet Performance. By John R. Henry and J. Buel Bennett.
2358. Effect of Vertical-Tail Area and Length on the Yawing Stability Characteristics of a Model Having a 45° Sweptback Wing. By William Letko.
2359. Floating Characteristics of a Plain and a Horn-Balanced Rudder at Spinning Attitudes as Determined from Rotary Tests on a Model of a Typical Low-Wing Personal-Owner Airplane. By William Bihrie, Jr.
2360. Effect of Tail Surfaces on the Base Drag of a Body of Revolution at Mach Numbers of 1.5 and 2.0. By J. Richard Spahr and Robert R. Dickey.
- No.
2361. Turbulence-Intensity Measurements in a Jet of Air Issuing from a Long Tube. By Barney H. Little, Jr., and Stafford W. Wilbur.
2362. Torsional Strength of Stiffened D-Tubes. By E. S. Kavanaugh and W. D. Drinkwater.
2363. On the Application of Mathieu Functions in the Theory of Subsonic Compressible Flow Past Oscillating Airfoils. By Eric Reissner.
2364. On Two-Dimensional Flow after a Curved Stationary Shock (with Special Reference to the Problem of Detached Shock Waves). By S. S. Shu.
2365. Analytical Evaluation of Aerodynamic Characteristics of Turbines with Nontwisted Rotor Blades. By William R. Slivka and David H. Silvern.
2366. Friction at High Sliding Velocities of Oxide Films on Steel Surfaces Boundary-Lubricated with Stearic-Acid Solutions. By Robert L. Johnson, Marshall B. Peterson, and Max A. Swikert.
2367. General Plastic Behavior and Approximate Solutions of Rotating Disk in Strain-Hardening Range. By M. H. Lee Wu.
2369. Torsion and Transverse Bending of Cantilever Plates. By Eric Reissner and Manuel Stein.
2370. Matrix Method of Determining the Longitudinal-Stability Coefficients and Frequency Response of an Aircraft from Transient Flight Data. By James J. Donegan and Henry A. Pearson.
2371. Possible Application of Blade Boundary-Layer Control to Improvement of Design and Off-Design Performance of Axial-Flow Turbomachines. By John T. Sinnette, Jr., and George R. Costello.
2372. Rectangular-Wind-Tunnel Blocking Corrections Using the Velocity-Ratio Method. By Rudolph W. Hensel.
2373. Practical Methods of Calculation Involved in the Experimental Study of an Autopilot and the Autopilot-Aircraft Combination. By Louis H. Smaus and Elwood C. Stewart.
2374. Effect of Initial Mixture Temperature on Flame Speed of Methane-Air, Propane-Air and Ethylene-Air Mixtures. By Gordon L. Dugger.
2375. On the Use of Coupled Modal Functions in Flutter Analysis. By Donald S. Woolston and Harry L. Runyan.
2376. Method for Analyzing Indeterminate Structures Stressed above Proportional Limit. By F. R. Steinbacher, C. N. Gaylord, and W. K. Rey.
2377. Effect of Fuel Immersion on Laminated Plastics. By W. A. Crouse, Margie Carickhoff and Margaret A. Fisher.
2378. Automatic Control Systems Satisfying Certain General Criteria on Transient Behavior. By Aaron S. Boksenbom and Richard Hood.
2379. An Investigation of the Effects of Jet-Outlet Cut-Off Angle on Thrust Direction and Body Pitching Moment. By James R. Blackaby.
2380. Effectiveness of Ceramic Coatings in Reducing Corrosion of Five Heat-Resistant Alloys by Lead-Bromide Vapors. By Dwight G. Moore and Mary W. Mason.
2381. Effect of Horizontal-Tail Location on Low Speed Static Longitudinal Stability and Damping in Pitch of a Model Having 45° Sweptback Wing and Tail Surfaces. By Jacob H. Lichtenstein.
2382. Effect of Horizontal-Tail Size and Tail Length on Low-Speed Static Longitudinal Stability and Damping in Pitch of a Model Having 45° Sweptback Wing and Tail Surfaces. By Jacob H. Lichtenstein.

- No.
2383. On a Solution of the Nonlinear Differential Equation for Transonic Flow Past a Wave-Shaped Wall. By Carl Kaplan.
2384. Preliminary Investigation of Wear and Friction Properties under Sliding Conditions of Materials Suitable for Cages of Rolling-Contact Bearings. By Robert L. Johnson, Max A. Swikert, and Edmond E. Bisson.
2385. Fundamental Aging Effects Influencing High-Temperature Properties of Solution-Treated Inconel X. By D. N. Frey, J. W. Freeman, and A. E. White.
2386. Studies of High-Temperature Protection of a Titanium-Carbide Ceramal by Chromium-Type Ceramic-Metal Coatings. By Dwight G. Moore, Stanley G. Benner and William N. Harrison.
2387. Three-Dimensional Unsteady Lift Problems in High-Speed Flight—The Triangular Wing. By Harvard Lomax, Max. A. Heaslet, and Franklyn B. Fuller.
2388. Axisymmetric Supersonic Flow in Rotating Impellers. By Arthur W. Goldstein.
2389. Fatigue Strengths of Aircraft Materials. Axial-Load Fatigue Tests on Notched Sheet Specimens of 24S-T3 and 75S-T6 Aluminum Alloys and of SAE 4130 Steel with Stress-Concentration Factors of 2.0 and 4.0. By H. J. Grover, S. M. Bishop, and L. R. Jackson.
2390. Fatigue Strengths of Aircraft Materials. Axial-Load Fatigue Tests on Notched Sheet Specimens of 24S-T3 and 75S-T6 Aluminum Alloys and of SAE 4130 Steel with Stress-Concentration Factor of 5.0. By H. J. Grover, S. M. Bishop, and L. R. Jackson.
2393. Flow through Cascades in Tandem. By William E. Spraglin.
2397. Influence of Tensile Strength and Ductility on Strengths of Rotating Disks in Presence of Material and Fabrication Defects of Several Types. By Arthur G. Holms, Joseph E. Jenkins, and Andrew J. Repko.
2398. Synthesis of Cyclopropane Hydrocarbons from Methylcyclopropyl Ketone. III—2-Cyclopropyl-1-Butene, *cis* and *trans* 2-Cyclopropyl-2-Butene, and 2-Cyclopropylbutane. By Vernon A. Slabey and Paul H. Wise.
2399. Applicability of the Hypersonic Similarity Rule to Pressure Distributions which Include the Effects of Rotation for Bodies of Revolution at Zero Angle of Attack. By Vernon J. Rossow.
2402. Construction and Use of Charts in Design Studies of Gas Turbines. By Sumner Alpert and Rose M. Litrenta.
2403. The Indicial Lift and Pitching Moment for a Sinking or Pitching Two-Dimensional Wing Flying at Subsonic or Supersonic Speeds. By Harvard Lomax, Max. A. Heaslet, and Loma Sluder.
2405. Investigation of NACA 64, 2-432 and 64, 3-440 Airfoil Sections with Boundary-Layer Control and an Analytical Study of Their Possible Applications. By Elmer A. Horton, Stanley F. Racisz, and Nicholas J. Paradiso.
2407. Method of Analysis for Compressible Flow Past Arbitrary Turbomachine Blades on General Surface of Revolution. By Chung-Hua Wu and Curtis A. Brown.
2408. Approximate Design Method for High-Solidity Blade Elements in Compressors and Turbines. By John D. Stanitz.
2409. Summary of Methods for Calculating Dynamic Lateral Stability and Response and for Estimating Lateral Stability Derivatives. By John P. Campbell and Marion O. McKinney.
- No.
2410. Analytical Investigation of Fully Developed Laminar Flow in Tubes with Heat Transfer with Fluid Properties Variable Along the Radius. By Robert G. Deissler.
2413. Flight Investigation of the Effect of Control Centering Springs on the Apparent Spiral Stability of a Personal-Owner Airplane. By John P. Campbell, Paul A. Hunter, Donald E. Hewes, and James B. Whitten.
2414. An Experimental Determination of the Critical Bending Moment of a Box Beam Stiffened by Posts. By Paul F. Barrett and Paul Seide.
2416. Theoretical Study of Some Methods for Increasing the Smoothness of Flight through Rough Air. By William H. Phillips and Christopher C. Kraft, Jr.
2418. Flow Separation Ahead of Blunt Bodies at Supersonic Speeds. By W. E. Moeckel.
2423. Theoretical Aerodynamic Characteristics of Bodies in a Free-Molecule-Flow Field. By Jackson R. Stalder and Vernon J. Zurick.
2424. Flight Investigation of the Effect of Transient Wing Response on Wing Strains of a Twin-Engine Transport Airplane in Rough Air. By Harry C. Mickleboro and C. C. Shuffelbarger.
2425. Plastic Stress-Strain Relations for 75S-T6 Aluminum Alloy Subjected to Biaxial Tensile Stresses. By Joseph Marin, B. H. Ulrich, and W. P. Hughes.
2431. Skin Friction of Incompressible Turbulent Boundary Layers Under Adverse Pressure Gradients. By Fabio R. Goldschmied.
2435. Direct-Reading Design Charts for 75S-T6 Aluminum-Alloy Flat Compression Panels Having Longitudinal Extruded Z-Section Stiffeners. By William A. Hickman and Norris F. Dow.
2438. Heat Transfer to Bodies in a High-Speed Rarefied-Gas Stream. By Jackson R. Stadler, Glen Goodwin, and Marcus O. Creager.
2441. Optical Methods Involving Light Scattering for Measuring Size and Concentration of Condensation Particles in Supercooled Hypersonic Flow. By Enoch J. Durbin.
2443. The Similarity Law for Hypersonic Flow about Slender Three-Dimensional Shapes. By Frank M. Hamaker, Stanford E. Neice, and A. J. Eggers, Jr.
2444. Effect of Stress-Solvent Crazing on Tensile Strength of Polymethyl Methacrylate. By B. M. Axilrod and Martha A. Sherman.
2490. Flight Investigation of Some Factors Affecting the Critical Tail Loads on Large Airplanes. By Harvey H. Brown.
2502. Examples of Three Representative Types of Airfoil-Section Stall at Low Speed. By George B. McCullough and Donald E. Gault.
2516. A Survey of Creep in Metals. By A. D. Schwoppe and L. R. Jackson.
2523. Rotogenerative Detection of Corrosion Currents. By Joseph B. McAndrew, William H. Colner, and Howard T. Francis.
2561. A Study of Poisson's Ratio in the Yield Region. By George Gerard and Sorrel Wildhorn.

TECHNICAL MEMORANDUMS¹

Part II—COMMITTEE ORGANIZATION AND MEMBERSHIP

The act of Congress approved March 3, 1915, establishing the National Advisory Committee for Aeronautics, as amended (U. S. Code, Supplement IV, title 50, sec. 151), provides that the Committee shall consist of 17 members appointed by the President, and shall include "two representatives of the Department of the Air Force; two representatives of the Department of the Navy, from the office in charge of naval aeronautics; two representatives of the Civil Aeronautics Authority; one representative of the Smithsonian Institution; one representative of the United States Weather Bureau; one representative of the National Bureau of Standards; the Chairman of the Research and Development Board of the National Military Establishment; and not more than seven other members selected from persons acquainted with the needs of aeronautical science, either civil or military, or skilled in aeronautical engineering or its allied sciences." These latter seven members serve for terms of 5 years. The representatives of the Government organizations serve for indefinite periods. All members serve as such without compensation.

Hon. Donald W. Nyrop, Chairman of the Civil Aeronautics Board, was appointed by President Truman a member of the National Advisory Committee for Aeronautics under date of April 24, 1951, succeeding Hon. Delos W. Rentzel, who resigned from the Committee because of his appointment as Under Secretary of Commerce for Transportation.

In accordance with law, Hon. Walter G. Whitman was appointed a member of the Committee August 9, 1951, following his appointment as Chairman of the Research and Development Board. Professor Whitman succeeded Hon. William Webster, who resigned from the Committee in July, concurrently with his resignation as Chairman of the RDB.

Because of his retirement from the United States Air Force, the membership of Maj. Gen. Gordon P. Saville on the Committee was terminated July 31, 1951. General Saville was serving as Deputy Chief of Staff, Development, in the Air Force. Another termination of membership resulted from the resignation of Dr. Edward U. Condon as Director of the National Bureau of Standards, effective September 30, 1951. Successors to General Saville and Dr. Condon on the Committee have not been appointed.

In accordance with the regulations governing the organization of the Committee as approved by the President, the Chairman and Vice Chairman are elected

annually, as are also the Chairman and Vice Chairman of the Executive Committee.

On October 12, 1951, Dr. Jerome C. Hunsaker was reelected Chairman of the NACA and of the Executive Committee, and Dr. Alexander Wetmore and Dr. Francis W. Reichelderfer were reelected Vice Chairman of the NACA and Vice Chairman of the Executive Committee, respectively.

COMMITTEE ON AERODYNAMICS

Dr. Theodore P. Wright, Cornell University, Chairman.
Capt. Walter S. Diehl, U. S. N. (Ret.), Vice Chairman.
Dr. Albert E. Lombard, Jr., Office, Directorate of Research and Development, U. S. Air Force.
Col. Jack A. Gibbs, U. S. A. F., Air Matériel Command.
Mr. F. A. Loudon, Bureau of Aeronautics, Department of the Navy.
Capt. M. R. Kelley, U. S. N. (Ret.), Bureau of Ordnance.
Brig. Gen. Leslie E. Simon, U. S. A., Chief, Ordnance Research and Development Division.
Mr. Harold D. Hoekstra, Civil Aeronautics Administration.
Dr. Hugh L. Dryden (ex officio).
Mr. Floyd L. Thompson, NACA Langley Aeronautical Laboratory.
Mr. Russell G. Robinson, NACA Ames Aeronautical Laboratory.
Prof. Jesse W. Beams, University of Virginia.
Mr. Edward J. Horkey, North American Aviation, Inc.
Mr. Clarence L. Johnson, Lockheed Aircraft Corp.
Mr. John G. Lee, United Aircraft Corp.
Mr. Grover Loening.
Dr. Clark B. Millikan, California Institute of Technology.
Dr. W. Bailey Oswald, Douglas Aircraft Co., Inc.
Mr. George S. Schairer, Boeing Airplane Co.
Prof. E. S. Taylor, Massachusetts Institute of Technology.
Mr. Robert J. Woods, Bell Aircraft Corp.

Mr. Milton B. Ames, Jr., Secretary

Subcommittee on Fluid Mechanics

Dr. Clark B. Millikan, California Institute of Technology, Chairman.
Dr. Frank L. Wattendorf, DCS/Development, Hq., U. S. Air Force.
Mr. L. S. Wasserman, Wright Air Development Center.
Capt. W. S. Diehl, U. S. N. (Ret.).
Dr. E. Bromberg, Office of Naval Research, Department of the Navy.
Dr. Raymond J. Seeger, Naval Ordnance Laboratory.
Mr. Joseph Sternberg, Ballistic Research Laboratories, Aberdeen Proving Ground.
Dr. G. B. Schubauer, National Bureau of Standards.
Dr. Carl Kaplan, NACA Langley Aeronautical Laboratory.
Mr. John Stack, NACA Langley Aeronautical Laboratory.
Mr. Robert T. Jones, NACA Ames Aeronautical Laboratory.
Mr. Walter G. Vincenti, NACA Ames Aeronautical Laboratory.

Dr. John C. Evvard, NACA Lewis Flight Propulsion Laboratory.
 Dr. William Bollay, North American Aviation, Inc.
 Dr. Francis H. Clauser, The Johns Hopkins University.
 Prof. Howard W. Emmons, Harvard University.
 Dr. Hans W. Liepmann, California Institute of Technology.
 Dr. C. C. Lin, Massachusetts Institute of Technology.
 Dr. William R. Sears, Cornell University.

Mr. E. O. Pearson, Jr., Secretary

Subcommittee on High-Speed Aerodynamics

Mr. John G. Lee, United Aircraft Corp., Chairman.
 Col. Robert M. Wray, U. S. A. F., Wright Air Development Center.
 Mr. H. L. Anderson, Wright Air Development Center.
 Commander Sydney S. Sherby, U. S. N., Bureau of Aeronautics.
 Dr. George L. Shue, Naval Ordnance Laboratory.
 Mr. C. L. Poor, III, Ballistic Research Laboratories, Aberdeen Proving Ground.
 Mr. Robert R. Gilruth, NACA Langley Aeronautical Laboratory.
 Mr. John Stack, NACA Langley Aeronautical Laboratory.
 Mr. H. Julian Allen, NACA Ames Aeronautical Laboratory.
 Mr. Abe Silverstein, NACA Lewis Flight Propulsion Laboratory.
 Mr. Irving L. Ashkenas, Northrop Aircraft, Inc.
 Mr. Benedict Cohn, Boeing Airplane Co.
 Mr. David S. Lewis, Jr., McDonnell Aircraft Corp.
 Mr. Harold Luskin, Douglas Aircraft Co., Inc.
 Prof. John R. Markham, Massachusetts Institute of Technology.
 Mr. C. E. Pappas, Republic Aviation Corp.
 Dr. Allen E. Puckett, Hughes Aircraft Co.
 Mr. William C. Schoolfield, United Aircraft Corp.
 Mr. H. A. Storms, Jr., North American Aviation, Inc.
 Mr. R. H. Widmer, Consolidated Vultee Aircraft Corp.

Mr. Edward C. Polhamus, Secretary

Subcommittee on Stability and Control

Capt. Walter S. Diehl, U. S. N. (Ret.), Chairman.
 Mr. Melvin Shorr, Wright Air Development Center.
 Mr. Gerald G. Kayten, Bureau of Aeronautics, Department of the Navy.
 Mr. Philippe W. Newton, U. S. Army Ordnance Corps.
 Mr. John A. Carran, Civil Aeronautics Administration.
 Mr. Thomas A. Harris, NACA Langley Aeronautical Laboratory.
 Mr. Harry J. Goett, NACA Ames Aeronautical Laboratory.
 Mr. George S. Graff, McDonnell Aircraft Corp.
 Mr. Herbert Harris, Jr., Sperry Gyroscope Co., Inc.
 Mr. Stuart A. Krieger, Northrop Aircraft, Inc.
 Mr. W. F. Milliken, Jr., Cornell Research Foundation, Inc.
 Mr. Dale D. Myers, North American Aviation, Inc.
 Prof. Courtland D. Perkins, Princeton University.
 Prof. Robert C. Seamans, Jr., Massachusetts Institute of Technology.
 Mr. Ralph H. Shick, Consolidated Vultee Aircraft Corp.
 Mr. Charles Tilgner, Jr., Grumman Aircraft Engineering Corp.
 Prof. Fred E. Weick, Agricultural and Mechanical College of Texas.

Mr. Jack D. Brewer, Secretary

Subcommittee on Internal Flow

Mr. Philip A. Colman, Lockheed Aircraft Corp., Chairman.
 Mr. Joseph Flatt, Wright Air Development Center.
 Capt. Walter Haaser, U. S. A. F., Wright Air Development Center.
 Commander R. L. Duncan, U. S. N., Office of Naval Research.

Mr. Palmer R. Wood, Bureau of Aeronautics, Department of the Navy.

Mr. C. L. Zakhartchenko, National Bureau of Standards.
 Mr. John V. Becker, NACA Langley Aeronautical Laboratory.
 Mr. E. A. Mossman, NACA Ames Aeronautical Laboratory.
 Mr. DeMarquis D. Wyatt, NACA Lewis Flight Propulsion Laboratory.
 Mr. J. S. Alford, General Electric Co.
 Mr. Leo A. Geyer, Grumman Aircraft Engineering Corp.
 Mr. Henry H. Hoadley, United Aircraft Corp.
 Dr. William J. O'Donnell, Republic Aviation Corp.
 Mr. Otto P. Prachar, General Motors Corp.
 Mr. Ascher H. Shapiro, Massachusetts Institute of Technology.
 Mr. Maurice A. Sulkin, North American Aviation, Inc.

Mr. Edward C. Polhamus, Secretary.

Subcommittee on Propellers for Aircraft

Mr. Thomas B. Rhines, Hamilton Standard Division, United Aircraft Corp., Chairman.
 Mr. Anthony F. Dernbach, Wright Air Development Center.
 Mr. Daniel A. Dickey, Wright Air Development Center.
 Mr. Ivan H. Driggs, Bureau of Aeronautics, Department of the Navy.
 Mr. John C. Morse, Civil Aeronautics Administration.
 Mr. Eugene C. Draley, NACA Langley Aeronautical Laboratory.
 Mr. Robert M. Crane, NACA Ames Aeronautical Laboratory.
 Mr. George W. Brady, Curtiss Wright Corp.
 Mr. Frank W. Caldwell, United Aircraft Corp.
 Mr. Wilfred W. Davies, United Air Lines, Inc.
 Mr. Ralph R. LaMotte, General Motors Corp.
 Mr. E. B. Maske, Jr., Consolidated Vultee Aircraft Corp.
 Mr. Robert B. Smith, Douglas Aircraft Co., Inc.

Mr. Ralph W. May, Secretary.

Subcommittee on Seaplanes

Mr. Grover Loening, Chairman.
 Mr. Joseph A. Ellis, Wright Air Development Center.
 Mr. J. H. Herald, Wright Air Development Center.
 Mr. Charles J. Daniels, Bureau of Aeronautics, Department of the Navy.
 Mr. F. W. S. Locke, Jr., Bureau of Aeronautics, Department of the Navy.
 Mr. Charlie C. Garrison, Office of Naval Research, Department of the Navy.
 Commander W. C. Fortune, U. S. N., David Taylor Model Basin.
 Commander John A. Ferguson, U. S. N., Naval Air Test Center, Patuxent.
 Capt. Donald B. MacDiarmid, U. S. C. G., U. S. Coast Guard Air Station, San Diego.
 Mr. John B. Parkinson, NACA Langley Aeronautical Laboratory.
 Mr. Robert B. Cotton, All American Airways, Inc.
 Dr. K. S. M. Davidson, Stevens Institute of Technology.
 Mr. J. D. Pierson, the Glenn L. Martin Co.
 Mr. William R. Ryan, Edo Corp.
 Mr. E. G. Stout, Consolidated Vultee Aircraft Corp.
 Mr. Henry B. Suydam, Grumman Aircraft Engineering Corp.

Mr. Ralph W. May, Secretary.

Subcommittee on Helicopters

Mr. Richard H. Prewitt, Prewitt Aircraft Co., Chairman.
 Mr. Bernard Lindenbaum, Wright Air Development Center.

Capt. Paul Simmons, Jr., U. S. A. F., Wright Air Development Center.
 Mr. Raymond A. Young, Bureau of Aeronautics, Department of the Navy.
 Commander Frank A. Erickson, U. S. C. G., U. S. Naval Air Station, Patuxent.
 Lt. Col. Jack L. Marinelli, F. A., Army Field Forces.
 Mr. Burdell L. Springer, Civil Aeronautics Administration.
 Mr. R. B. Maloy, Civil Aeronautics Administration.
 Mr. Richard C. Dingeldein, NACA Langley Aeronautical Laboratory.
 Mr. F. B. Gustafson, NACA Langley Aeronautical Laboratory.
 Mr. Michael E. Gluhareff, Sikorsky Aircraft, United Aircraft Corp.
 Mr. Bartram Kelley, Bell Aircraft Corp.
 Mr. Rene H. Miller, Massachusetts Institute of Technology.
 Mr. Robert R. Osborn, McDonnell Aircraft Corp.
 Mr. F. N. Piasecki, Piasecki Helicopter Corp.
 Mr. N. M. Stefano, Hughes Aircraft Co.

Mr. Leslie E. Schneider, Secretary.

Special Subcommittee on the Upper Atmosphere

Dr. Harry Wexler, U. S. Weather Bureau, Chairman.
 Col. Benjamin G. Holzman, U. S. A. F., Office, Deputy Chief of Staff for Matériel, Department of the Air Force.
 Dr. Sverre Pettersen, Air Weather Service, U. S. Air Force.
 Capt. Walter S. Diehl, U. S. N. (Ret.).
 Dr. Homer E. Newell, Jr., Naval Research Laboratory.
 Dr. O. R. Wulf, California Institute of Technology.
 Dr. W. G. Brombacher, National Bureau of Standards.
 Mr. William J. O'Sullivan, NACA Langley Aeronautical Laboratory.
 Dr. Carl W. Gartlein, Cornell University.
 Dr. B. Gutenberg, California Institute of Technology.
 Dr. Harvey Hall, Office of Naval Research, Department of the Navy.
 Prof. Bernhard Haurwitz, New York University.
 Dr. Joseph Kaplan, University of California.
 Dr. W. W. Kellogg, The Rand Corp.
 Dr. Zdenek Kopal, Massachusetts Institute of Technology.
 Dr. C. L. Pekeris, the Institute for Advanced Study.
 Dr. J. A. Van Allen, The Johns Hopkins University.
 Dr. Harry W. Wells, Carnegie Institution of Washington.
 Dr. Fred L. Whipple, Harvard University.

Mr. Leslie E. Schneider, Secretary.

COMMITTEE ON POWER PLANTS FOR AIRCRAFT

Mr. Ronald M. Hazen, Allison Division, General Motors Corp., Chairman.
 Prof. E. S. Taylor, Massachusetts Institute of Technology, Vice Chairman.
 Col. Norman C. Appold, U. S. A. F., Chief, Power Plant Laboratory.
 Col. Paul F. Nay, U. S. A. F., Chief, Propulsion Branch, Aircraft Division.
 Capt. E. M. Condra, Jr., U. S. N., Bureau of Aeronautics.
 Mr. Stephen Rolle, Civil Aeronautics Administration.
 Dr. Hugh L. Dryden (ex officio).
 Mr. Abe Silverstein, NACA Lewis Flight Propulsion Laboratory.
 Mr. Frank W. Davis, Consolidated Vultee Aircraft Corp.
 Dr. Louis G. Dunn, California Institute of Technology.
 Mr. William M. Holaday, Socony Vacuum Oil Co., Inc.
 Mr. R. P. Kroon, Westinghouse Electric Corp.
 Mr. William C. Lawrence, American Airlines, Inc.

Mr. Wilton G. Lundquist, Wright Aeronautical Corp., Division of Curtiss-Wright Corp.
 Mr. Wright A. Parkins, Pratt and Whitney Aircraft Division, United Aircraft Corp.
 Mr. George S. Schairer, Boeing Airplane Co.
 Mr. Raymond W. Young, Reaction Motors, Inc.

Mr. William H. Woodward, Secretary.

Subcommittee on Aircraft Fuels

Dr. J. Bennett Hill, Sun Oil Co., Chairman.
 Lt. Col. J. H. Lee, U. S. A. F., Propulsion Branch, Aircraft Division.
 Maj. M. W. Shayeson, U. S. A. F., Wright Air Development Center.
 Comdr. Robert F. Wadsworth, U. S. N., Bureau of Aeronautics.
 Mr. Ralph S. White, Civil Aeronautics Administration.
 Dr. L. C. Gibbons, NACA Lewis Flight Propulsion Laboratory.
 Dr. D. P. Barnard, Standard Oil Co. of Indiana.
 Mr. A. J. Blackwood, Standard Oil Development Co.
 Mr. J. L. Cooley, California Research Corp.
 Mr. S. D. Heron, Ethyl Corp.
 Mr. W. M. Holaday, Socony-Vacuum Oil Co., Inc.
 Mr. C. R. Johnson, Shell Oil Co.
 Mr. Melvin H. Young, Wright Aeronautical Corp., Division of Curtiss-Wright Corp.
 Dr. W. E. Kuhn, The Texas Co.
 Mr. O. E. Rodgers, Aviation Gas Turbine Division, Westinghouse Electric Corp.
 Mr. Earle A. Ryder, Pratt and Whitney Aircraft Division, United Aircraft Corp.
 Mr. Harold M. Trimble, Phillips Petroleum Co.

Mr. Henry E. Alquist, Secretary.

Subcommittee on Combustion

Dr. Bernard Lewis, Bureau of Mines, Chairman.
 Dr. D. G. Samaras, Wright Air Development Center.
 Mr. Garrett L. Wander, Wright Air Development Force.
 Mr. N. N. Tilley, Bureau of Aeronautics, Department of the Navy.
 Mr. Edward H. Seymour, Office of Naval Research, Department of the Navy.
 Dr. Ernest F. Flock, National Bureau of Standards.
 Dr. Walter T. Olson, NACA Lewis Flight Propulsion Laboratory.
 Mr. Edmund D. Brown, Pratt and Whitney Aircraft Division, United Aircraft Corp.
 Dr. Alfred G. Cattaneo, Shell Development Co.
 Prof. Newman A. Hall, University of Minnesota.
 Dr. John P. Longwell, Standard Oil Development Co.
 Mr. A. J. Nerad, General Electric Co.
 Dr. Robert N. Pease, Princeton University.
 Mr. Edwin P. Walsh, Westinghouse Electric Corp.
 Prof. Glenn C. Williams, Massachusetts Institute of Technology.
 Dr. Kurt Wohl, University of Delaware.

Mr. Henry E. Alquist, Secretary.

Subcommittee on Lubrication and Wear

Mr. E. M. Phillips, General Electric Co., Chairman.
 Mr. J. Josteller, Wright Air Development Center.
 Mr. Robert C. Sheard, Wright Air Development Center.
 Mr. Charles C. Singleterry, Bureau of Aeronautics, Department of the Navy.
 Dr. William Zisman, Naval Research Laboratory, Department of the Navy.

Mr. Edmond E. Bisson, NACA Lewis Flight Propulsion Laboratory.
 Mr. Richard W. Blair, Wright Aeronautical Corp., Division of Curtiss-Wright Corp.
 Dr. John T. Burwell, Jr., Horizons, Inc.
 Dr. Merrell R. Fenske, Pennsylvania State College.
 Mr. Daniel Gurney, Marlin-Rockwell Corp.
 Dr. Robert G. Larsen, Shell Development Co.
 Mr. C. J. McDowall, Allison Division, General Motors Corp.
 Mr. Joseph Palsulich, Cleveland Graphite Bronze Co.
 Mr. Earle A. Ryder, Pratt and Whitney Aircraft Division, United Aircraft Corp.
 Mr. C. H. Stockdale, Westinghouse Electric Corp.
 Dr. Haakon Styri, SKF Industries, Inc.
 Mr. Arthur F. Underwood, General Motors Corp.
 Mr. W. Andrew Wright, Sun Oil Co.

Mr. William H. Woodward, Secretary.

Subcommittee on Engine Performance and Operation

Mr. Arnold H. Redding, Westinghouse Electric Corp., Chairman.
 Mr. Opie Chenoweth, Wright Air Development Center.
 Mr. C. C. Sorgen, Bureau of Aeronautics, Department of the Navy.
 Mr. Bruce T. Lundin, NACA Lewis Flight Propulsion Laboratory.
 Dr. John L. Barnes, North American Aviation, Inc.
 Prof. Gordon S. Brown, Massachusetts Institute of Technology.
 Mr. Dimitrius Gerdan, Allison Division, General Motors Corp.
 Mr. John Karanik, Grumman Aircraft Engineering Corp.
 Dr. Roy E. Marquardt, Marquardt Aircraft Co.
 Dr. William J. O'Donnell, Republic Aviation Corp.
 Mr. Erol F. Pierce, Wright Aeronautical Corp., Division of Curtiss-Wright Corp.
 Mr. Perry W. Pratt, Pratt and Whitney Aircraft Division, United Aircraft Corp.
 Mr. E. E. Stoeckly, General Electric Co.
 Mr. Lon Storey, Jr., Lockheed Aircraft Corp.
 Mr. Lee R. Woodworth, The Rand Corp.

Mr. Richard S. Cesaro, Secretary.

Subcommittee on Compressors and Turbines

Prof. Howard W. Emmons, Harvard University, Chairman.
 Mr. Ernest C. Simpson, Wright Air Development Center.
 Mr. Robert W. Pinnes, Bureau of Aeronautics, Department of the Navy.
 Commander R. L. Duncan, U. S. N., Office of Naval Research, Department of the Navy.
 Mr. John R. Erwin, NACA Langley Aeronautical Laboratory.
 Mr. Robert O. Bullock, NACA Lewis Flight Propulsion Laboratory.
 Mr. Kenneth Campbell, Wright Aeronautical Corp., Division of Curtiss-Wright Corp.
 Mr. Walter Doll, Pratt and Whitney Aircraft Division, United Aircraft Corp.
 Mr. Jack C. Fethers, Allison Division, General Motors Corp.
 Mr. R. S. Hall, General Electric Co.
 Dr. Frank E. Marble, California Institute of Technology.
 Mr. Charles A. Meyer, Westinghouse Electric Corp.
 Prof. George F. Wislicenus, The Johns Hopkins University.

Mr. Guy N. Ullman, Secretary.

Subcommittee on Heat-Resisting Materials

Mr. Arthur W. F. Green, General Motors Corp., Chairman.
 Mr. J. B. Johnson, Wright Air Development Center.
 Mr. Nathan E. Promisel, Bureau of Aeronautics, Department of the Navy.
 Mr. Benjamin Pinkel, NACA Lewis Flight Propulsion Laboratory.
 Mr. W. L. Badger, General Electric Co.
 Mr. Howard C. Cross, Battelle Memorial Institute.
 Mr. P. G. DeHuff, Jr., Westinghouse Electric Corp.
 Mr. Russell Franks, Union Carbide & Carbon Corp.
 Mr. Herbert J. French, International Nickel Co.
 Prof. Nicholas J. Grant, Massachusetts Institute of Technology.
 Mr. Alvin J. Herzig, Climax Molybdenum Co. of Michigan.
 Dr. L. H. Milligan, Norton Co.
 Dr. Gunther Mohling, Allegheny Ludlum Steel Corp.
 Mr. Rudolf H. Thielemann, Pratt and Whitney Aircraft Division, United Aircraft Corp.

Mr. William H. Woodward, Secretary.

Special Subcommittee on Rocket Engines

Dr. Maurice J. Zucrow, Purdue University, Chairman.
 Mr. C. W. Schnare, Wright Air Development Center.
 Commander K. C. Childers, Jr., U. S. N., Bureau of Aeronautics, Department of the Navy.
 Capt. Levering Smith, U. S. N., Naval Ordnance Test Station, Inyokern.
 Mr. Joseph L. Gray, Office of the Chief of Ordnance, Department of the Army.
 Mr. Paul R. Hill, NACA Langley Aeronautical Laboratory.
 Mr. John L. Sloop, NACA Lewis Flight Propulsion Laboratory.
 Mr. Richard B. Canright, California Institute of Technology.
 Mr. R. Bruce Foster, Bell Aircraft Corp.
 Mr. Stanley L. Gendler, The Rand Corp.
 Dr. George E. Moore, General Electric Co.
 Mr. Thomas E. Myers, North American Aviation, Inc.
 Mr. Jack H. Sheets, Curtiss-Wright Corp.
 Dr. Robert J. Thompson, Jr., M. W. Kellogg Co.
 Dr. Paul F. Winternitz, Reaction Motors, Inc.
 Mr. David A. Young, Aerojet Engineering Corp.

Mr. Henry E. Alquist, Secretary.

COMMITTEE ON AIRCRAFT CONSTRUCTION

Dr. Arthur E. Raymond, Douglas Aircraft Co., Inc., Chairman.
 Mr. R. L. Templin, Aluminum Co. of America, Vice Chairman.
 Mr. E. H. Schwartz, Wright Air Development Center.
 Capt. Robert S. Hatcher, U. S. N., Bureau of Aeronautics, Department of the Navy.
 Mr. Albert A. Vollmecke, Civil Aeronautics Administration.
 Dr. Hugh L. Dryden (ex officio).
 Dr. Henry J. E. Reid, NACA Langley Aeronautical Laboratory.
 Mr. Carlton Bioletti, NACA Ames Aeronautical Laboratory.
 Prof. Raymond L. Bisplinghoff, Massachusetts Institute of Technology.
 Prof. Emerson W. Conlon, University of Michigan.
 Dr. C. C. Furnas, Cornell Aeronautical Laboratory, Inc.
 Dr. Alexander A. Kartveli, Republic Aviation Corp.
 Mr. W. C. Mentzer, United Air Lines, Inc.
 Mr. George Snyder, Boeing Airplane Co.
 Mr. Luther P. Spalding, North American Aviation, Inc.
 Mr. Charles R. Strang, Douglas Aircraft Co., Inc.

Mr. Franklyn W. Phillips, Secretary.

Subcommittee on Aircraft Structures

Mr. Charles R. Strang, Douglas Aircraft Co., Inc., Chairman.
 Mr. J. W. Farrell, Wright Air Development Center.
 Mr. Joseph Kelley, Jr., Wright Air Development Center.
 Commander L. S. Chambers, U. S. N., Bureau of Aeronautics, Department of the Navy.
 Mr. Ralph L. Creel, Bureau of Aeronautics, Bureau of Aeronautics, Department of the Navy.
 Mr. William T. Shuler, Civil Aeronautics Administration.
 Mr. Samuel Levy, National Bureau of Standards.
 Dr. Eugene E. Lundquist, NACA Langley Aeronautical Laboratory.
 Prof. W. H. Gale, Massachusetts Institute of Technology.
 Mr. Ira G. Hedrick, Grumman Aircraft Engineering Corp.
 Dr. Nicholas J. Hoff, Polytechnic Institute of Brooklyn.
 Mr. Jerome F. McBrearty, Lockheed Aircraft Corp.
 Mr. Francis MeVay, Republic Aviation Corp.
 Mr. John H. Meyer, McDonnell Aircraft Corp.
 Prof. Ernest E. Sechler, California Institute of Technology.
 Mr. R. L. Templin, Aluminum Co. of America.

Mr. Melvin G. Rosche, Secretary.

Subcommittee on Aircraft Loads

Mr. George Snyder, Boeing Airplane Co., Chairman.
 Mr. Joseph H. Harrington, Wright Air Development Center.
 Mr. Edward J. Lunney, Wright Air Development Center.
 Commander Donald J. Hardy, U. S. N., Bureau of Aeronautics, Department of the Navy.
 Mr. John P. Wamser, Bureau of Aeronautics, Department of the Navy.
 Mr. Burdell L. Springer, Civil Aeronautics Administration.
 Mr. Philip Donely, NACA Langley Aeronautical Laboratory.
 Mr. Manley J. Hood, NACA Ames Aeronautical Laboratory.
 Mr. Albert Epstein, Republic Aviation Corp.
 Mr. F. D. Jewett, The Glenn L. Martin Co.
 Mr. Jerome F. McBrearty, Lockheed Aircraft Corp.
 Mr. Alfred I. Sibila, Chance Vought Aircraft, United Aircraft Corp.
 Mr. K. E. Van Every, Douglas Aircraft Co., Inc.

Mr. R. Fabian Goranson, Secretary.

Subcommittee on Vibration and Flutter

Prof. Raymond L. Bisplinghoff, Massachusetts Institute of Technology, Chairman.
 Mr. Howard A. Magrath, Wright Air Development Center.
 Mr. L. S. Wasserman, Wright Air Development Center.
 Capt. Walter S. Diehl, U. S. N. (Ret.).
 Mr. James E. Walsh, Bureau of Aeronautics, Department of the Navy.
 Mr. Robert Rosenbaum, Civil Aeronautics Administration.
 Mr. I. E. Garrick, NACA Langley Aeronautical Laboratory.
 Mr. Albert Erickson, NACA Ames Aeronautical Laboratory.
 Mr. Samuel S. Manson, NACA Lewis Flight Propulsion Laboratory.
 Dr. William E. Cox, Northrop Aircraft, Inc.
 Dr. J. M. Frankland, Chance Vought Aircraft, United Aircraft Corp.
 Mr. Martin Goland, Midwest Research Institute.
 Mr. E. B. Kinnaman, Boeing Airplane Co.
 Mr. Raymond A. Pepping, McDonnell Aircraft Corp.

Mr. Harvey H. Brown, Secretary.

Subcommittee on Aircraft Structural Materials

Mr. Edgar H. Dix, Jr., Aluminum Co. of America, Chairman.
 Mr. J. B. Johnson, Wright Air Development Center.
 Mr. James E. Sullivan, Bureau of Aeronautics, Department of the Navy.
 Dr. Gordon M. Kline, National Bureau of Standards.
 Mr. James E. Dougherty, Jr., Civil Aeronautics Administration.
 Mr. Frank B. Bolte, North American Aviation, Inc.
 Prof. Maxwell Gensamer, Columbia University.
 Mr. O. W. Loudenslager, Goodyear Aircraft Corp.
 Dr. J. C. McDonald, The Dow Chemical Co.
 Dr. Robert F. Mehl, Carnegie Institute of Technology.
 Mr. Paul P. Mozley, Lockheed Aircraft Corp.
 Mr. David G. Reid, Chance Vought Aircraft Division, United Aircraft Corp.
 Mr. D. H. Ruhnke, Republic Steel Corp.

Mr. Charles V. Krebs, Secretary.

COMMITTEE ON OPERATING PROBLEMS

Mr. William Littlewood, American Airlines, Inc., Chairman.
 Mr. Charles Froesch, Eastern Air Lines, Inc., Vice Chairman.
 Col. Baskin R. Lawrence, Jr., U. S. A. F., Wright Air Development Center.
 Col. J. Francis Taylor, Jr., U. S. A. F., Wright Air Development Center.
 Commander A. L. Maccubbin, U. S. N., Bureau of Aeronautics, Department of the Navy.
 Maj. Gen. William H. Tunner, U. S. A., Hq., Military Air Transport Service.
 Dr. F. W. Reichelderfer, Chief, U. S. Weather Bureau.
 Mr. George W. Haldeman, Civil Aeronautics Administration.
 Mr. Donald M. Stuart, Civil Aeronautics Administration.
 Dr. Hugh L. Dryden (ex officio).
 Mr. Melvin N. Gough, NACA Langley Aeronautical Laboratory.
 Mr. Eugene J. Manganiello, NACA Lewis Flight Propulsion Laboratory.
 Mr. P. R. Bassett, Sperry Gyroscope Co., Inc., Division of the Sperry Corp.
 Mr. M. G. Beard, American Airlines, Inc.
 Mr. John G. Borger, Pan American World Airways, Inc.
 Mr. Warren T. Dickinson, Douglas Aircraft Co., Inc.
 Mr. Robert E. Johnson, Wright Aeronautical Corp., Division of Curtiss-Wright Corp.
 Mr. Jerome Lederer.
 Dr. Ross A. McFarland, Harvard School of Public Health.
 Mr. W. C. Mentzer, United Air Lines, Inc.

Dr. T. L. K. Smull, Secretary.

Subcommittee on Meteorological Problems

Dr. F. W. Reichelderfer, U. S. Weather Bureau, Chairman.
 Brig. Gen. W. O. Senter, U. S. A. F., Air Weather Service.

Part III—FINANCIAL REPORT

Appropriations for the fiscal year 1951.—Funds and contract authority in the following amounts were appropriated for the Committee for the fiscal year 1951 in the General Appropriation Act, 1951, approved September 6, 1950, and the Second Supplemental Appropriation Act, 1951, approved January 6, 1951:

Salaries and expenses..... \$45, 750, 000
Construction and equipment of laboratory facilities:

Funds to continue financing of fiscal year 1949 program:

Langley Aeronautical Laboratory..... \$6, 000, 000
Lewis Flight Propulsion Laboratory..... 4, 000, 000

10, 000, 000

Funds to continue financing of fiscal year 1950 program:

Langley Aeronautical Laboratory..... \$2, 771, 988
Pilotless Aircraft Research Station..... 478, 012
Lewis Flight Propulsion Laboratory..... 1, 750, 000

5, 000, 000

Funds to start financing of fiscal year 1951 program:

Langley Aeronautical Laboratory..... \$200, 000
Ames Aeronautical Laboratory..... 300, 000
Lewis Flight Propulsion Laboratory..... 1, 818, 000

2, 318, 000

Total appropriated funds, fiscal year 1951.....

\$63, 068, 000

Contract authority for remaining obligations necessary to complete fiscal year 1951 program:

Langley Aeronautical Laboratory..... \$2, 300, 000
Ames Aeronautical Laboratory..... 8, 700, 000

Total contract authority, fiscal year 1951..... \$11, 000, 000

Obligations incurred against the fiscal year 1951 appropriated funds and contract authority are listed below, together with the unobligated balances remaining on August 31, 1951. The figures shown for salaries and expenses include the costs for personal services, travel, transportation, communication, utility services, printing and reproduction, contractual services, supplies and equipment.

Salaries and expenses:

NACA Headquarters..... \$1, 081, 842
Langley Aeronautical Laboratory..... 17, 631, 974
Pilotless Aircraft Research Station..... 803, 904

Salaries and expenses—Continued

High-Speed Flight Research Station..... \$919, 281
Ames Aeronautical Laboratory..... 7, 535, 318
Western Coordination Office..... 18, 485
Lewis Flight Propulsion Laboratory..... 16, 416, 186
Wright-Patterson Coordination Office..... 10, 424
Research contracts—educational institutions..... 779, 649
Services performed by National Bureau of Standards and Forest Products Laboratory... 209, 501
Unobligated balance..... 343, 436

Total appropriated funds, salaries and expenses.....

45, 750, 000

Construction and equipment of laboratory facilities:

Funds to continue financing of fiscal year 1949 program:

Langley Aeronautical Laboratory..... \$5, 858, 400
Lewis Flight Propulsion Laboratory..... 3, 999, 508
Unobligated balance..... 142, 092

10, 000, 000

Funds to continue financing of fiscal year 1951 program:

Langley Aeronautical Laboratory..... \$2, 755, 553
Pilotless Aircraft Research Station..... 473, 863
Lewis Flight Propulsion Laboratory..... 1, 708, 099
Unobligated balance..... 62, 485

5, 000, 000

Funds to start financing of fiscal year 1951 program:

Langley Aeronautical Laboratory..... \$198, 222
Ames Aeronautical Laboratory..... 300, 000
Lewis Flight Propulsion Laboratory..... 1, 676, 796
Unobligated balance..... 142, 982

2, 318, 000

Total appropriated funds, fiscal year 1951.....

\$63, 068, 000

Contract authority for remaining obligations necessary to complete fiscal year 1951 program:

Langley Aeronautical Laboratory..... \$1, 497, 744
Ames Aeronautical Laboratory..... 3, 177, 786
Unobligated balance..... 16, 324, 470

Total contract authority, fiscal year 1951..... \$11, 000, 000

¹ These unobligated balances remain available for obligation in the fiscal year 1952.

Appropriation for the Unitary Wind Tunnel Plan Act.—Funds in the amount of \$75,000,000 were appropriated in the Deficiency Appropriation Act, 1950, approved June 29, 1950, for the construction of wind tunnels authorized in the Unitary Wind Tunnel Plan Act of 1949 (Public Law 415, 81st Cong., approved October 27, 1949). These funds are available until expended. Allotments and obligations as of June 30, 1951, are as follows:

	Allotments	Obligations as of June 30, 1951
Langley Aeronautical Laboratory----	\$14,917,000	\$6,440,860
Ames Aeronautical Laboratory-----	27,227,000	9,904,944
Lewis Flight Propulsion Laboratory--	32,856,000	9,905,955
Total-----	\$75,000,000	\$26,251,759

Appropriations for the fiscal year 1952.—The major allotments of the funds appropriated for the Committee for the fiscal year 1952 in the Independent Offices Appropriation Act, 1952 approved August 31, 1951, are given below:

Salaries and Expenses-----	\$49,250,000
Construction and equipment of labora- tory facilities:	
Funds to complete financing of fiscal year 1949 program:	
Langley Aeronautical Labora- tory-----	\$372,800
Lewis Flight Propulsion Lab- oratory-----	550,000
	922,800

	Allotments	Obligations as of June 30, 1951
Construction and equipment of labora- tory facilities—Continued		
Funds to complete financing of fiscal year 1950 program:		
Langley Aeronautical Labora- tory-----	\$3,493,524	
Lewis Flight Propulsion Lab- oratory-----	1,500,000	
		\$4,993,524
Funds to continue financing of fiscal year 1951 program:		
Langley Aeronautical Labora- tory-----	\$1,233,676	
Ames Aeronautical Labora- tory-----	4,500,000	
		5,733,676
Funds to completely finance fiscal year 1952 program:		
Langley Aeronautical Labora- tory-----	\$730,000	
Pilotless Aircraft Research Station-----	90,000	
High-Speed Flight Research Station-----	4,000,000	
Ames Aeronautical Labora- tory-----	1,480,000	
Lewis Flight Propulsion Lab- oratory-----	350,000	
		6,650,000
Total appropriated funds, fiscal year 1952-----		\$67,600,000

REPORT 1003

CORRELATION OF PHYSICAL PROPERTIES WITH MOLECULAR STRUCTURE FOR SOME DICYCLIC HYDROCARBONS HAVING HIGH THERMAL-ENERGY RELEASE PER UNIT VOLUME¹

By P. H. WISE, K. T. SERIJAN, and I. A. GOODMAN

SUMMARY

As part of a program to study the correlation between molecular structure and physical properties of high-density hydrocarbons, the net heats of combustion, melting points, boiling points, densities, and kinematic viscosities of some hydrocarbons in the 2-*n*-alkylbiphenyl, 1,1-diphenylalkane, α , ω -diphenylalkane, 1,1-dicyclohexylalkane, and α , ω -dicyclohexylalkane series are presented. Comparisons are made on the following three bases:

1. As members of an homologous series in which the compounds have similar structures and differ in molecular weight
2. As isomers with the same molecular weight and molecular formula but different molecular structure

3. As compounds with the same carbon skeleton but different molecular formulas due to hydrogenation of the aromatic rings

The three series of aromatic hydrocarbons, 2-*n*-alkylbiphenyl, 1,1-diphenylalkane, and α , ω -diphenylalkane, did not show great differences in heat of combustion per unit volume. These series averaged 20 percent higher than typical aircraft fuels of AN-F-58 specification with respect to this property. The two series of dicyclohexyl hydrocarbons, 1,1-dicyclohexylalkane and α , ω -dicyclohexylalkane, had somewhat lower heats of combustion, but still averaged about 13 percent higher than AN-F-58 fuel.

Each series followed its own characteristic pattern in the relation of melting point and structure. The general trend was toward lower melting points by addition of a side chain to the parent hydrocarbon. With two exceptions, the dicyclohexyl compounds melted at lower temperatures than the analogous aromatic hydrocarbons.

The molecular weight had a greater influence on boiling point than the molecular structure. The α , ω -diphenylalkane series, however, showed a more rapid rate of increase in boiling point with increasing molecular weight than the other series of aromatic hydrocarbons.

In these three closely related homologous series of aromatic hydrocarbons, the molecular weight had a greater effect on viscosity than the molecular structure when the substituent groups were all normal alkyl in type. The cyclohexyl derivatives had viscosities 40 to 200 percent higher than the analogous aromatic hydrocarbons.

INTRODUCTION

High-speed aircraft are volume-limited because of the design requirements of thin wings and small fuselages; the fuel-storage space is therefore restricted. In evaluating fuels for such aircraft, one of the important properties is the heat of combustion per unit volume. Fuels with high heat of combustion per unit volume would be valuable in providing increased flight range.

A survey of the literature pertaining to properties of hydrocarbons was therefore made at the NACA Lewis laboratory with particular emphasis on the heat of combustion per unit volume. The hydrocarbons were compared as homologous series to determine which features of molecular structure might be expected to be associated with high heat of combustion per unit volume. The net heats of combustion of the normal paraffin, normal alkylcyclohexane, and normal alkylbenzene hydrocarbons of seven to fourteen carbon atoms vary from 824,000 to 977,000 Btu per cubic foot. For an equivalent number of carbon atoms, the comparison of net heat of combustion is: *n*-alkylbenzene > *n*-alkylcyclohexane > *n*-paraffin. It is evident that a ring structure increases the heat of combustion per unit volume and that the unsaturated ring in benzene has an advantage over the saturated cyclohexane ring. These values of net heat of combustion were calculated from data obtained in references 1 and 2.

Compounds from these three homologous series are principal constituents of the aircraft fuels AN-F-48, AN-F-32a, and AN-F-58, which are currently used and are described by the specifications in references 3, 4, and 5, respectively. Fuels that were purchased under these specifications and used at the Lewis laboratory were found to have the following values of net heat of combustion: AN-F-48, 823,000; AN-F-32a, 960,000; and AN-F-58, 894,000 Btu per cubic foot. These values vary depending upon the source of supply; they have been arbitrarily chosen, however, as a standard for comparing the hydrocarbons discussed herein.

The advantage of an aromatic ring in a molecule led to the investigation of the properties of biphenyl, diphenylmethane, and naphthalene. Each of these compounds has two aromatic rings per molecule, and the net heats of com-

¹ Supersedes NACA TN 2081, "Correlation of Physical Properties with Molecular Structure for Dicyclic Hydrocarbons. I—2-*n*-Alkylbiphenyl, 1,1-Diphenylalkane, α , ω -Diphenylalkane, 1,1-Dicyclohexylalkane, and α , ω -Dicyclohexylalkane, Series," by P. H. Wise, K. T. Serijan, and I. A. Goodman, 1950.

bustion (references 1 and 2) are 1,096,000; 1,110,000; and 1,210,000 Btu per cubic foot, respectively. These values represent an average increase of 30 percent over AN-F-48, 15 percent over AN-F-32a, and 20 percent over AN-F-58. On the basis of heat of combustion, these three hydrocarbons would be desirable fuels; however, they have relatively high melting points and are unsuitable for use as liquid fuels. If the introduction of various alkyl groups into these hydrocarbons would sufficiently lower the melting points without reducing the heat of combustion per unit volume, a superior fuel would be obtained. The data on many of these alkyl derivatives are incomplete and in some cases inaccurate; consequently, they cannot be used as a basis for a reliable analysis of the usefulness of these high-energy hydrocarbons as aircraft-engine fuels.

FIGURE 1.—Structure of hydrocarbons.

An investigation was therefore undertaken at the Lewis laboratory during 1945 to determine the effects of systematic alteration in structure of dicyclic-aromatic-type molecules on the following important properties of the fuel: net heat of combustion per unit volume, heat of combustion per unit weight, melting point, boiling point, and viscosity.

Comparisons are made on the following three bases:

1. As members of an homologous series in which the compounds have similar structures and differ in molecular weight
2. As isomers with the same molecular weight and molecular formula but different molecular structure
3. As compounds with the same carbon skeleton but different molecular formulas due to hydrogenation of the aromatic rings

METHOD AND APPARATUS

The compounds discussed represent five homologous series of hydrocarbons; namely, the 2-*n*-alkylbiphenyl; 1,1-diphenylalkane; 1,1-dicyclohexylalkane; α,ω -diphenylalkane; and α,ω -dicyclohexylalkane series. The structures of these hydrocarbons are illustrated in figure 1. The normal alkyl groups illustrated at the bottom of the figure were selected to study the effect of increasing the chain length of these substituent groups when they are attached to the parent

hydrocarbons, biphenyl and diphenylmethane. From diphenylmethane two series are developed, the 1,1-diphenylalkane series by adding the alkyl group as a side chain attached to the carbon atom between the phenyl groups and the α,ω -diphenylalkane series by lengthening the chain of carbon atoms between the two rings.

The saturated, or cyclohexyl, derivatives corresponding to the aromatic compounds are also illustrated. They are prepared by hydrogenation of the pure aromatic compounds. It is known that the saturated compounds generally have lower melting points and burn with less carbon formation than the corresponding aromatic hydrocarbons. On the other hand, saturated hydrocarbons have higher viscosities and lower net heats of combustion per unit volume than their aromatic counterparts. Inasmuch as many properties must be considered in selecting a fuel, it seemed advisable to study the saturated compounds to determine accurately the extent of the changes produced by hydrogenation.

With the exceptions noted in the tables of properties, the compounds were synthesized and purified, or purified from commercial stocks, at the Lewis laboratory; the properties were then determined. Before final measurement of the properties was made, precautions were taken to ascertain that the high purity essential for the accurate study of properties was attained.

The time-temperature melting curves were determined with a platinum resistance thermometer and a G-2 Mueller bridge with accessory equipment and by methods described in reference 6, and the melting points were determined from the curves according to the graphical method described in reference 7. Densities were determined by use of a gravimetric balance according to the method of reference 8, and the refractive indices were measured with a Bausch & Lomb precision oil-model five-plate instrument. The boiling points were determined by the use of a platinum resistance thermometer in an apparatus modified from that described in reference 9. The system was pressurized with dry air from a surge tank and held at constant pressure by adjusting a continuous bleed. The kinematic viscosities were determined in viscosimeters that had been calibrated with National Bureau of Standards standard viscosity samples H-5, H-7, D-7, or L-17. The A.S.T.M. procedure of reference 10 was followed. The net heats of combustion were determined according to reference 11 in an oxygen bomb calorimeter that had been calibrated on Bureau of Standards benzoic acid.

The magnitude of the uncertainties is estimated as follows: melting point, 0.02°C ; density, 0.00005 gram per milliliter; refractive index, 0.0002; boiling point, 0.1°C ; kinematic viscosity, 0.5 percent of determined value relative to 1.007 centistokes for water at 20°C ; and net heat of combustion, ± 100 Btu per pound, which is equivalent to 10 to 15 kilogram-calories per mole for these compounds.

The precision of measurements is: freezing point, $\pm 0.003^\circ \text{C}$; density, ± 0.00002 to ± 0.00003 gram per milliliter; refractive index, ± 0.0001 ; boiling point, $\pm 0.04^\circ \text{C}$; kinematic viscosity, 0.2 percent of determined value; and net heat of combustion, ± 60 Btu per pound.

DISCUSSION OF RESULTS

2-*n*-ALKYLBIPHENYL HYDROCARBONS

The physical properties of the 2-*n*-alkylbiphenyl hydrocarbons are presented in table I (a) and the heat-of-combustion data are given in table I (b). The data are plotted in figure 2. The comparison of molecular structure with net heat of combustion in Btu per cubic foot for the 2-*n*-alkylbiphenyl hydrocarbons is shown in figure 2 (a). The parent hydrocarbon, biphenyl, has the highest value, 1,096,000 Btu per cubic foot. The first member of the series, 2-methylbiphenyl, is slightly lower at 1,078,000 Btu per cubic foot. Each carbon atom that is subsequently added to lengthen the side chain causes some decrease in

FIGURE 2.—Variation of properties with structure of 2-*n*-alkylbiphenyl hydrocarbons.

FIGURE 2.—Concluded. Variation of properties with structure of 2-*n*-alkylbiphenyl hydrocarbons.

the net heat of combustion per unit volume, and 2-*n*-butylbiphenyl with four carbon atoms in the side chain has a value of 1,048,000 Btu per cubic foot, which is a loss of 4.3 percent from biphenyl. This value is, however, still 17 percent higher than a typical AN-F-58 aircraft fuel.

The melting- and boiling-point comparisons of this series of hydrocarbons are shown in figure 2 (b). Biphenyl melts at 69.2° C, and each member of the series has a lower melting point as the molecular weight and side-chain length are increased. The fourth member of the series, 2-*n*-butylbiphenyl, melts at -13.71° C, a decrease of 83° C from the value for biphenyl.

The boiling-point curve shows the reverse trend, increasing from 255.0° to 291.20° C in the transition from the parent hydrocarbon to 2-*n*-butylbiphenyl.

The viscosities of these hydrocarbons at three temperatures are compared in figure 2 (c). The trend is the same as for the boiling point; an increase in molecular weight by lengthening the side chain is accompanied by an increase in viscosity. At 0° C (32° F), where the viscosity of biphenyl cannot be determined because the compound is a solid, there is an increase of 85 percent from 2-methylbiphenyl to 2-*n*-butylbiphenyl. The effect of temperature is even more pronounced. The average increase in viscosity for the individual members of the series is 200 percent when the temperature is lowered from 98.89° C (210° F) to 37.78° C (100° F) and about 1300 percent when the temperature is 0° C (32° F) compared with 98.89° C (210° F). No data were obtained below 0° C (32° F) because most of these compounds are crystalline solids at temperatures only a few degrees below this temperature.

1,1-DIPHENYLALKANE AND 1,1-DICYCLOHEXYLALKANE HYDROCARBONS

The properties of these two series of hydrocarbons are shown in table II and plotted in figure 3. By using data from these two series, it is possible to compare compounds that have like arrangement of the carbon skeleton and different hydrogen-carbon ratios. The data for the two series are therefore plotted in the same figures, with solid

lines representing the aromatic series and dashed lines, the saturated series.

The net heat of combustion in Btu per cubic foot is compared with the molecular structure in figure 3 (a). Biphenyl is considered to be the parent hydrocarbon and is compared with the other members of this series, as was the case with

FIGURE 3.—Variation of properties with structure of 1,1-diphenyl and 1,1-dicyclohexylalkane hydrocarbons.

the 2-*n*-alkylbiphenyl hydrocarbons. The carbon atom added between the two rings in diphenylmethane results in a 2-percent loss in Btu per cubic foot. A small decrease in net heat of combustion per cubic foot is observed with each carbon atom that is added to the side chain. The over-all loss from biphenyl to 1,1-diphenylbutane is, however, only 3.3 percent.

In plotting the dicyclohexyl derivatives, each point indicates the value for the hydrogenated compound with the carbon skeleton corresponding to that of the aromatic compound immediately below the point on the figure. The average decrease in net heat of combustion per unit volume is 5 percent when each saturated compound is compared with its aromatic counterpart. This decrease is due to the lower density of the hydrogenated derivatives in comparison with the aromatic hydrocarbons.

The melting points of these two series of hydrocarbons are shown in figure 3 (b). The aromatic series shows a consistent decrease from biphenyl (melting point, 69.2° C) to 1,1-diphenylbutane (melting point, -28.4° C) except for one member, 1,1-diphenylpropane, which melts at 13.3° C. This melting point is higher than that of the compound preceding or following it in the series.

The saturated compounds melt at lower temperatures than the corresponding aromatic hydrocarbons except in the comparison of the butane derivatives where the saturated compound has a higher melting point than the diphenyl derivative.

The boiling points of the two series (fig. 3 (c)) show a regular increase with lengthening of the carbon chain. The difference between analogous members of the two series decreases with increasing chain length. The first members of the two series differ about 16° C; the last three pairs differ 1° to 3° C. The diphenyl compounds have consistently higher boiling points than the saturated derivatives.

The increase in viscosity due to hydrogenation of the aromatic nuclei to saturated rings is observed by comparing the viscosities of these two series in figure 3 (d). The saturated derivatives average 48 percent higher at 98.89° C (210° F) and 200 percent higher at 0° C (32° F). Both series show consistent increases in viscosity with increase in chain length.

α,ω -DIPHENYLALKANE AND α,ω -DICYCLOHEXYLALKANE HYDROCARBONS

The properties of the two series of α,ω -dicyclicalkanes are tabulated in table III and plotted in figure 4. With the two α,ω -dicyclicalkane hydrocarbon series of compounds, it is again possible to compare the aromatic and the saturated derivatives. The data for net heat of combustion are shown in figure 4 (a). In the aromatic series, a decrease of 3.5 percent in Btu per cubic foot is observed as the carbon chain between the two rings is lengthened. The values for the saturated series are quite uniform and average about 5 percent lower than the aromatic hydrocarbons. The saturated compounds, however, average about 12 percent higher than an AN-F-58 aircraft fuel on the basis of heat of combustion per unit volume.

The two series follow similar patterns in melting-point behavior as the length of the carbon chain is increased

(fig. 4 (b)). The melting points of the saturated compounds are consistently lower than those of the corresponding aromatic hydrocarbons except for the 1,3-dicyclic compounds, in which case the aromatic derivative is slightly lower.

The boiling-point data for these compounds, shown in figure 4 (c), indicate uniform increases in both series as the carbon chain between the rings is lengthened. The boiling points of the aromatic compounds are consistently higher than those of the saturated derivatives with the corresponding carbon skeleton.

(a) Net heat of combustion.
(b) Melting point.

FIGURE 4.—Variation of properties with structure of α,ω -diphenylalkane and α,ω -dicyclohexylalkane hydrocarbons.

Comparison of viscosities in these series, plotted in figure 4 (d), is necessarily incomplete because the aromatic compounds have relatively high melting points and are solids at several of the temperatures of measurement. The aromatic compounds are liquids at 98.89° C (210° F), and the vis-

cosity increases slowly with increasing chain length. At this temperature, the viscosity values of the saturated compounds average 43 percent higher than the corresponding aromatic compounds. At the lower temperatures some data points are missing, but the trends are the same.

COMPARISON OF THREE AROMATIC SERIES

The comparisons that have been presented were made on the basis of homologous series in which the molecular structure of the individual members of a series differed only by the length of the aliphatic carbon chain in the molecule. Each series started from the common parent hydrocarbon, biphenyl. A comparison of the effect of structure on the properties can also be made by studying the properties of the hydrocarbons, one from each series, that have a common molecular formula. An example would be those with the formula $C_{14}H_{14}$, that is, 2-ethylbiphenyl, 1,1-diphenylethane, and 1,2-diphenylethane. In order to make this comparison, the properties of each series have been plotted in figure 5. The properties are plotted as the ordinates and the number of carbon atoms added to the parent hydrocarbon is plotted as the abscissa.

The effect of structure on heat of combustion per unit volume is shown in figure 5 (a). The ratio of Btu per cubic foot to the corresponding value for a typical AN-F-58 aircraft fuel (table I, footnote d) is used as the ordinate rather than the absolute value determined for the compounds. This ratio is a measure of the advantage to be gained in heat of combustion per unit volume by using fuels of this type. The 1,1-diphenylalkane series decreased less rapidly in heat of combustion per unit volume than the other two series as the carbon chain was lengthened. None of these series, however, decreased more than 6 percent from the parent hydrocarbon, and they are all about 20 percent higher than AN-F-58 with respect to this property.

The divergent behavior of these three series with respect to their melting points is illustrated in figure 5 (b). The 2-*n*-alkylbiphenyl series has increasingly lower melting points as the side chain is increased in length. The other series are characterized by alternate lower and higher melting points as the series are extended.

The curves of figure 5 (c) show that the molecular weight has more influence on boiling point than the structure, because the boiling points are quite closely grouped. The α,ω -diphenylalkane series does show, however, a more rapid rate of increase in boiling point with increase in chain length than the other two series. The boiling point of 1,3-diphenylpropane is higher than those of 1,1-diphenylbutane and 2-*n*-butylbiphenyl, which have one more carbon atom per molecule.

The viscosities of the three series of hydrocarbons at the three temperatures of measurement are plotted in figure 5 (d). The viscosities depend more upon the molecular weight than upon the molecular structure in these closely related series. As the molecular weight increases, the differences between the viscosity values of the isomers in the three series diminish.

SUMMARY OF RESULTS

A study of the variation of properties with change in molecular structure in the homologous series—2-*n*-alkylbiphenyl; 1,1-diphenylalkane; α,ω -diphenylalkane; 1,1-dicyclohexylalkane; and α,ω -dicyclohexylalkane—indicated the following trends:

1. The net heat of combustion per unit volume decreased an average of about 5 percent as the molecular weight was increased from the parent hydrocarbon, biphenyl, to 1,3-diphenylpropane and to the $C_{16}H_{18}$ isomers in the 2-*n*-alkylbiphenyl and 1,1-diphenylalkane hydrocarbon series. All three series averaged about 20 percent higher than an AN-F-58 aircraft fuel with respect to this property.

2. In the two series of hydrogenated compounds, 1,1-dicyclohexylalkane and α,ω -dicyclohexylalkane, the values of net heat of combustion per unit volume were somewhat lower than the analogous aromatic compounds and did not vary greatly throughout the series. The series averaged about 13 percent higher than an AN-F-58 fuel.

3. Each of the aromatic series followed a characteristic pattern of melting-point variation as the molecular weight was increased. The general trend was toward lower melting points as the size of the alkyl substituent was increased, but exceptions to this general statement were observed in the α,ω -diphenylalkane series and the 1,1-diphenylalkane series.

4. Hydrogenation of the aromatic nuclei to saturated rings lowered the melting point in all of the cases except two.

5. The boiling points of the investigated hydrocarbons were influenced more by their molecular weight than by molecular structure. The α,ω -diphenylalkane series, however, did show a more rapid rate of increase of boiling point with increase in molecular weight than the 1,1-diphenylalkane and 2-*n*-alkylbiphenyl series. The saturated derivatives had boiling points slightly lower than those of the corresponding diphenyl compounds.

6. In the three aromatic series, the viscosity increased uniformly with increase in molecular weight. The viscosity values of the isomers were nearly equal in many cases; it was therefore concluded that with the types of molecule studied the molecular weight influenced viscosity to a greater extent than did molecular structure. The saturated hydrocarbons had much higher viscosities than the corresponding diphenyl compounds, with the increases ranging from approximately 40 to 200 percent.

7. Of the compounds investigated, 1,1-diphenylbutane

had the lowest melting point, -28.4°C . This compound had a net heat of combustion of 1,059,000 Btu per cubic foot, which is 18 percent greater than the AN-F-58 fuel selected for comparison.

REPORT 1004

A LIFT-CANCELLATION TECHNIQUE IN LINEARIZED SUPERSONIC-WING THEORY¹

By HAROLD MIRELS

SUMMARY

A lift-cancellation technique is presented for determining load distributions on thin wings at supersonic speeds. The loading on a wing having a prescribed plan form is expressed as the loading of a known related wing (such as a two-dimensional or a triangular wing) minus the loading of an appropriate cancellation wing.

A general expression is derived for the load distribution over a cancellation wing. The expression is valid when the plan-form edge (on the cancellation wing) separating a region of zero upwash from a region of known loading is everywhere subsonically inclined to the free stream. The boundary conditions can be satisfied for both subsonic leading and subsonic trailing plan-form edges on the prescribed wing.

The lift-cancellation technique can be used to find the loading on a large variety of wings. Applications to swept wings having curvilinear plan forms and to wings having reentrant side edges are indicated.

INTRODUCTION

The method of lift cancellation for obtaining the lift distribution on thin wings at supersonic speeds was first suggested in reference 1. The lift distribution on a given wing is determined by canceling excess lift, through the use of a "cancellation wing," on a related plan form having a known loading. This approach has been applied by several authors (for example, references 2 to 4). The expressions provided in reference 1 are applicable for wings that can be generated by the superposition of conical fields.

A procedure is presented in reference 5 for determining lift on a more general class of plan forms than can be handled by conical superposition. The method utilizes a surface distribution of doublets and an inversion by means of Abel's integral equation and is equivalent to a lift cancellation.

This report, prepared at the NACA Lewis laboratory, retains certain features of reference 5 (that is, the use of a surface distribution of doublets and an inversion by means of Abel's integral equation), whereas other features are simplified and generalized. The simplification consists in eliminating steps in the procedure for obtaining lift distributions. The generalization consists in determining a solution that can be made to satisfy the boundary conditions for either a subsonic leading edge or a subsonic trailing edge (Kutta condition). The method of reference 5 yields only the Kutta

solution. The lift-cancellation technique developed herein is illustrated by several examples.

In a concurrent investigation (reference 6), source distributions and integral-equation formulations are applied to obtain the loading on a special series of cancellation wings. Reference 7 employs some of these cancellation wings for the determination of lift and moments on swept wings.

THEORY

The usual assumptions of an inviscid fluid and small perturbations are made. The velocity field consists of the free-stream velocity U (taken in the positive x -direction) plus the perturbation velocities u , v , and w . The wing boundary conditions are specified in the $z=0$ plane.

The local lift coefficient ΔC_p may be expressed in terms of Δu ; that is,

$$\Delta C_p = \frac{p_B - p_T}{q} = \frac{2(u_T - u_B)}{U} = \frac{2\Delta u}{U} \quad (1)$$

(All symbols used in this report are defined in appendix A.) Inasmuch as the local lift coefficient is directly proportional to Δu , Δu will be referred to as "lift" in later developments.

LIFT-CANCELLATION METHOD

The lift distribution on a given wing is to be determined by canceling excess lift on a related wing with a known loading. The method is illustrated in figure 1. The wing for which the lift distribution is desired is shown in figure 1 (a). The solution can be expressed as the two-dimensional wing (fig. 1 (b)) minus a cancellation wing (fig. 1 (c)). The loading in region I of the cancellation wing equals the loading in the corresponding region of the two-dimensional wing and the upwash w in region II of the cancellation wing is zero. The two-dimensional wing minus the cancellation wing satisfies the boundary conditions for the flow about the given wing and is the desired solution.

The fundamental problem in the lift-cancellation method is then to determine the lift in region II of a cancellation wing subject to the condition $w=0$ in this region and with the assumption of a known loading in region I. Solution of this problem is presented in the following sections.

DERIVATION OF LIFT-CANCELLATION EQUATIONS

The lift distribution in region II will be expressed in terms of quantities in region I.

¹ Supersedes NACA TN 2145, "Lift-Cancellation Technique in Linearized Supersonic-Wing Theory" by Harold Mirels, 1950.

Consider the cancellation wing shown in figure 2. The portion of the leading edge to the left of the origin coincides with a Mach line. The portion of the leading edge to the right (designated $r=r_1(s)$) is shown as a supersonic edge, although no restrictions as to a subsonic or supersonic edge are imposed. (A plan-form edge is subsonic or supersonic depending on whether the component of the free stream normal to the edge is subsonic or supersonic.) The line designated $r=r_2(s)$ separates region I and region II and is

(a) Given wing.
(b) Two-dimensional wing.
(c) Cancellation wing.

FIGURE 1.—Superposition to obtain lift on given wing by canceling lift on two-dimensional wing. (Given wing equals two-dimensional wing minus cancellation wing.)

assumed to be subsonically inclined to the free stream at all points. This line corresponds to a plan-form edge of the wing for which the lift distribution is desired.

General solution for $\Delta\varphi$ on cancellation wing.—The upwash field in the $z=0$ plane (associated with an arbitrary distribution of vorticity Δu and Δv) may be written, from reference 8,

$$w = \frac{\beta^2}{2\pi} \int \int_{\tau} \frac{[(y-y_0)\Delta v + (x-x_0)\Delta u] dx_0 dy_0}{[(x-x_0)^2 - \beta^2(y-y_0)^2]^{3/2}} \quad (2)$$

The symbol $\int$ designates the finite part of an infinite integral, as defined in reference 9. Application of the finite-part

concept to linearized supersonic-wing theory and the evaluation of the finite part of an infinite integral are discussed in references 8 and 10. For the present, it will suffice to state the fundamental definition of the finite part of an integral with a $3/2$ -power singularity, namely,

$$\int_a^x \frac{f(x_0) dx_0}{(x-x_0)^{3/2}} = \int_a^x \frac{[f(x_0) - f(x)] dx_0}{(x-x_0)^{3/2}} - \frac{2f(x)}{(x-a)^{1/2}} \quad (3)$$

By a transformation to the Mach coordinates of reference 11,

$$\left. \begin{aligned} x &= \frac{\beta}{M} (s+r) & r &= \frac{M}{2\beta} (x-\beta y) \\ y &= \frac{1}{M} (s-r) & s &= \frac{M}{2\beta} (x+\beta y) \\ \text{elemental area} &= \frac{2\beta}{M^2} dr ds \end{aligned} \right\} \quad (4)$$

equation (2) becomes

$$w = \frac{M}{8\pi} \int \int_{\tau} \frac{\left[(s-s_0) \frac{\partial \Delta\varphi}{\partial s_0} + (r-r_0) \frac{\partial \Delta\varphi}{\partial r_0} \right] dr_0 ds_0}{[(r-r_0)(s-s_0)]^{3/2}} \quad (5)$$

Upon substitution of the limits of integration, as indicated in figure 2,

$$w = \frac{M}{8\pi} \left\{ \int_0^s \frac{ds_0}{(s-s_0)^{3/2}} \int_{r_1(s_0)}^r \frac{\frac{\partial \Delta\varphi}{\partial r_0} dr_0}{(r-r_0)^{1/2}} + \int_0^s \frac{ds_0}{(s-s_0)^{1/2}} \int_{r_1(s_0)}^r \frac{\frac{\partial \Delta\varphi}{\partial s_0} dr_0}{(r-r_0)^{3/2}} \right\} \quad (6)$$

FIGURE 2.—Typical cancellation wing.

Integrating by parts, noting that $\Delta\varphi=0$ at $r_0=r_1(s_0)$, and recalling the definition of the finite part (equation (3)) yield

$$\begin{aligned} \int_{r_1(s_0)}^r \frac{\frac{\partial \Delta\varphi}{\partial r_0} dr_0}{(r-r_0)^{1/2}} &= \lim_{r_0 \rightarrow r} \left\{ \frac{\Delta\varphi}{(r-r_0)^{1/2}} \right\}_{r_1(s_0)} - \frac{1}{2} \int_{r_1(s_0)}^r \frac{\Delta\varphi dr_0}{(r-r_0)^{3/2}} \\ &= -\frac{1}{2} \int_{r_1(s_0)}^r \frac{\Delta\varphi dr_0}{(r-r_0)^{3/2}} \end{aligned} \quad (7)$$

Thus,

$$\int_0^s \frac{ds_o}{(s-s_o)^{3/2}} \int_{r_1(s_o)}^r \frac{\partial \Delta \varphi}{\partial r_o} \frac{dr_o}{(r-r_o)^{1/2}} \equiv -\frac{1}{2} \int_0^s \frac{ds_o}{(s-s_o)^{3/2}} \int_{r_1(s_o)}^r \frac{\Delta \varphi dr_o}{(r-r_o)^{3/2}} \quad (8)$$

Similarly, reversing the order of integration (with appropriate changes in limits of integration), integrating by parts, and then returning to the original order of integration establish the identity

$$\int_0^s \frac{ds_o}{(s-s_o)^{1/2}} \int_{r_1(s_o)}^r \frac{\partial \Delta \varphi}{\partial s_o} \frac{dr_o}{(r-r_o)^{3/2}} \equiv -\frac{1}{2} \int_0^s \frac{ds_o}{(s-s_o)^{3/2}} \int_{r_1(s_o)}^r \frac{\Delta \varphi dr_o}{(r-r_o)^{3/2}} \quad (9)$$

The right side of equations (8) and (9) are identical. Equation (6) can now be written as

$$w = -\frac{M}{8\pi} \int_0^s \frac{ds_o}{(s-s_o)^{3/2}} \int_{r_1(s_o)}^r \frac{\Delta \varphi dr_o}{(r-r_o)^{3/2}} \quad (10)$$

For points in region II, $w=0$ and equation (10) becomes

$$0 = \int_0^s \frac{ds_o}{(s-s_o)^{3/2}} \int_{r_1(s_o)}^r \frac{\Delta \varphi dr_o}{(r-r_o)^{3/2}} \quad (11a)$$

or

$$0 = \int_0^s \frac{G(r, s_o) ds_o}{(s-s_o)^{3/2}} \quad (11b)$$

where

$$G(r, s_o) = \int_{r_1(s_o)}^r \frac{\Delta \varphi dr_o}{(r-r_o)^{3/2}} \quad (12)$$

Equation (11b) is an integral equation for the unknown function $G(r, s_o)$. The solution (appendix B) is

$$G(r, s_o) = 0 \quad (13)$$

Thus,

$$\int_{r_1(s_o)}^r \frac{\Delta \varphi dr_o}{(r-r_o)^{3/2}} = \int_{r_1(s_o)}^{r_2(s_o)} \frac{\Delta \varphi_I dr_o}{(r-r_o)^{3/2}} + \int_{r_2(s_o)}^r \frac{\Delta \varphi_{II} dr_o}{(r-r_o)^{3/2}} = 0$$

or

$$\int_{r_2(s_o)}^r \frac{\Delta \varphi_{II} dr_o}{(r-r_o)^{3/2}} = - \int_{r_1(s_o)}^{r_2(s_o)} \frac{\Delta \varphi_I dr_o}{(r-r_o)^{3/2}} \quad (14)$$

The right side of equation (14) will be considered known. Equation (14) is then an integral equation for $\Delta \varphi_{II}$. The solution (appendix B) is

$$\Delta \varphi_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta \varphi_I dr_o}{(r-r_o) \sqrt{r_2(s)-r_o}} \quad (15)$$

Equation (15) indicates that the doublet strength in region II, namely $\Delta \varphi_{II}$, can be obtained by a line integration along $s_o=s$ in region I. The geometric interpretation of the various terms in equation (15) is shown in figure 3 (a).

It can be shown, by expanding $\Delta \varphi_I$ about $r_o=r_2(s)$, that equation (15) yields a continuous solution ($\Delta \varphi_{II}=\Delta \varphi_I$) at $r=r_2(s)$. (A discontinuity in $\Delta \varphi$ implies a lifting line (reference 12) and is unrealistic.)

FIGURE 3.—Geometric interpretation of terms in equations (17a) and (17b).

General solution for load distribution on cancellation wing.—The load distribution in region II can be expressed as

$$\begin{aligned} \Delta u_{II} &= \frac{\partial \Delta \varphi_{II}}{\partial x} = \frac{\partial \Delta \varphi_{II}}{\partial r} \frac{\partial r}{\partial x} + \frac{\partial \Delta \varphi_{II}}{\partial s} \frac{\partial s}{\partial x} \\ &= \frac{M}{2\beta} \left(\frac{\partial}{\partial r} + \frac{\partial}{\partial s} \right) \Delta \varphi_{II} \end{aligned}$$

or, from equation (15),

$$\frac{2\beta}{M} \Delta u_{II} = \left(\frac{\partial}{\partial r} + \frac{\partial}{\partial s} \right) \left[\frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta \varphi_I dr_o}{(r-r_o) \sqrt{r_2(s)-r_o}} \right] \quad (16)$$

Differentiation yields (see appendix C)

$$\begin{aligned} \Delta u_{II} &= \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o) \sqrt{r_2(s)-r_o}} - \\ &\quad \frac{1 - \frac{dr_2(s)}{ds}}{2\beta\pi \sqrt{r-r_2(s)}} \int_{r_1(s)}^{r_2(s)} \frac{(\beta \Delta u_I - \Delta v_I) dr_o}{\sqrt{r_2(s)-r_o}} \end{aligned} \quad (17a)$$

Equation (17a) is the desired expression for the lift distribution in region II in terms of quantities in region I.

Consider Δu_{II} to consist of two components, $\Delta u_{II}'$ and $\Delta u_{II}''$, where $\Delta u_{II}'$ and $\Delta u_{II}''$ are the first and second terms on the right side of equation (17a), respectively. Investigation of the integrals indicates that at $r=r_2(s)$, $\Delta u_{II}'=\Delta u_I$; whereas $\Delta u_{II}''$, in general, has a half-order singularity.

However, $\partial\Delta\varphi_I/\partial r_o$ must be continuous in the vicinity of $r_2(s)$. (The perturbation velocities on the basic wing can be discontinuous only along Mach lines or along plan-form edges. Inasmuch as $r=r_2(s)$ is neither of these cases, all derivatives of $\Delta\varphi_I$ must be continuous in the vicinity of $r=r_2(s)$.) When the Kutta condition is imposed, $\partial\Delta\varphi_{II}/\partial r_o$ is therefore also continuous (and bounded) in the neighborhood of $r=r_2(s)$. Then with the use of a mean value for $\partial\Delta\varphi_{II}/\partial r_o$,

$$\lim_{r \rightarrow r_2(s)} \left[\int_{r_2(s)}^r \frac{\frac{\partial\Delta\varphi_{II}}{\partial r_o} dr_o}{(r-r_o)^{1/2}} \right] = \lim_{r \rightarrow r_2(s)} \left[\left(\frac{\partial\Delta\varphi_{II}}{\partial r_o} \right)_{(r_2(s) < r_o < r)} \int_{r_2(s)}^r \frac{dr_o}{(r-r_o)^{1/2}} \right] = 0 \quad (22)$$

Therefore,

$$\int_{r_1(s)}^{r_2(s)} \frac{\frac{\partial\Delta\varphi_I}{\partial r_o} dr_o}{[r_2(s)-r_o]^{1/2}} = 0 \quad (23)$$

which was to be proved.

The solution for Δu_{II} that satisfies the Kutta condition at $r=r_2(s)$ is then, from equations (17a) and (23),

$$\Delta u_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \quad (24a)$$

for the wing of figure 3 (a). Similarly,

$$\Delta u_{II} = \frac{\sqrt{s-s_2(r)}}{\pi} \int_{s_1(r)}^{s_2(r)} \frac{\Delta u_I ds_o}{(s-s_o)\sqrt{s_2(r)-s_o}} \quad (24b)$$

for the wing of figure 3 (b).

An alternative derivation of equations (24a) and (24b) (appendix D) indicates that only solutions satisfying the Kutta condition will result from the integral equation formulation of reference 5.

Sidewash in region II.—An expression for Δv_{II} can be obtained by differentiating equation (15) with respect to y . The result is

$$\Delta v_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta v_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} + \frac{1 + \frac{dr_2(s)}{ds}}{2\pi\sqrt{r-r_2(s)}} \int_{r_1(s)}^{r_2(s)} \frac{\beta\Delta u_I - \Delta v_I}{\sqrt{r_2(s)-r_o}} dr_o$$

Similarly, for region II to the right of region I,

$$\Delta v_{II} = \frac{\sqrt{s-s_2(r)}}{\pi} \int_{s_1(r)}^{s_2(r)} \frac{\Delta v_I ds_o}{(s-s_o)\sqrt{s_2(r)-s_o}} + \frac{1 + \frac{ds_2(r)}{ds}}{2\pi\sqrt{s-s_2(r)}} \int_{s_1(r)}^{s_2(r)} \frac{\beta\Delta u_I + \Delta v_I}{\sqrt{s_2(r)-s_o}} ds_o$$

When the Kutta condition applies, these equations become, respectively,

$$\Delta v_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta v_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}}$$

and

$$\Delta v_{II} = \frac{\sqrt{s-s_2(r)}}{\pi} \int_{s_1(r)}^{s_2(r)} \frac{\Delta v_I ds_o}{(s-s_o)\sqrt{s_2(r)-s_o}}$$

It should be noted that when $r=r_2(s)$ corresponds to a subsonic trailing edge, Δv_I , as well as Δv_{II} , is not generally known. The preceding expressions are therefore primarily useful for those problems where $r=r_2(s)$ corresponds to a subsonic leading edge.

APPLICATIONS

The loading in region II of a cancellation wing is given by the line integrals of equation (17a) or (17b). When the Kutta condition is imposed at a subsonic trailing edge, the expressions reduce to equations (24a) and (24b). These equations can be used to find the load distribution on a large variety of wings. Wings with curvilinear plan forms or arbitrary camber are examples. In each case, however, the solution for the related wing must be known.

The equations are applied in several illustrative examples. Only the solution associated with the cancellation wing is considered. The complete solution consists of the loading of the related wing minus the loading of the cancellation wing.

LEADING-EDGE AND SIDE-EDGE CANCELLATIONS

In leading-edge and side-edge cancellations, the lift to be canceled is upstream or to the side of the plan form for which the loading is desired (figs. 5 and 6).

Tip region of swept wing.—The loading in the region influenced by the side edge (II_a and II_b of fig. 5) of a swept wing having a subsonic leading and a supersonic trailing edge can be obtained by canceling excess lift on a triangular wing. The Kutta condition is applied across the portion of $r=r_2(s)$ influencing region II_b. The lift to be canceled in region I is (reference 13, equation (23))

$$\Delta u_I = \frac{H\theta^2 x}{\sqrt{\theta^2 x^2 - \beta^2 y^2}} = \frac{H\theta^2(s+r)}{\sqrt{\theta^2(s+r)^2 - (s-r)^2}} \quad (25)$$

where H and θ are constants defined in appendix A. The doublet distribution in region I_a, again from reference 13, is

$$\Delta\varphi_{I_a} = H\sqrt{\theta^2 x^2 - \beta^2 y^2} = \frac{\beta H}{M} \sqrt{\theta^2(s+r)^2 - (s-r)^2}$$

from which

$$\Delta v_{I_a} = \frac{\partial\Delta\varphi_{I_a}}{\partial y} = \frac{-H\beta^2 y}{\sqrt{\theta^2 x^2 - \beta^2 y^2}} = \frac{-H\beta(s-r)}{\sqrt{\theta^2(s+r)^2 - (s-r)^2}} \quad (26)$$

The sidewash distribution in region I_b (that is, Δv_{I_b}) could be found by an integration of the type indicated in equation (18b). A knowledge of Δv_{I_b} , however, is unnecessary in

the present problem because the Kutta condition is applied for region II_b.

The loading in region II_a is obtained by substituting equations (25) and (26), with r replaced by r_o , into equation (17a), which yields

$$\Delta u_{II_a} = \frac{H\theta^2\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{(s+r_o)dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}\sqrt{\theta^2(s+r_o)^2-(s-r_o)^2}} - \frac{H\left[1-\frac{dr_2(s)}{ds}\right]}{2\pi\sqrt{r-r_2(s)}} \int_{r_1(s)}^{r_2(s)} \frac{[\theta^2(s+r_o)+(s-r_o)]dr_o}{\sqrt{r_2(s)-r_o}\sqrt{\theta^2(s+r_o)^2-(s-r_o)^2}} \quad (27)$$

FIGURE 5.—Cancellation for obtaining loading in tip region of swept wing having supersonic trailing edges.

For region II_b, the Kutta condition applies and

$$\Delta u_{II_b} = \frac{H\theta^2\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{(s+r_o)dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}\sqrt{\theta^2(s+r_o)^2-(s-r_o)^2}} \quad (28)$$

Equations (27) and (28) reduce to elliptic integrals of the first, second, and third kinds upon transforming the variable of integration from r_o to ω_o according to the relation

$$r_o = \frac{1}{1+\theta} [(1-\theta)s + a_2\omega_o^2] \quad (29)$$

where

$$a_2 = (1+\theta)r_2(s) - (1-\theta)s$$

Equations (27) and (28) may then be written

$$\Delta u_{II_a} = \frac{H\theta^2\sqrt{r-r_2(s)}}{\pi\sqrt{s\theta}} \left\{ \frac{(s+r)(1+\theta)}{a} \left[\Pi\left(\frac{\pi}{2}, n, k\right) - \Pi(\phi, n, k) \right] - \left[F\left(\frac{\pi}{2}, k\right) - F(\phi, k) \right] \right\} - \frac{H\sqrt{s\theta}\left[1-\frac{dr_2(s)}{ds}\right]}{\pi\sqrt{r-r_2(s)}} \left\{ 2 \left[E\left(\frac{\pi}{2}, k\right) - E(\phi, k) \right] - \left[F\left(\frac{\pi}{2}, k\right) - F(\phi, k) \right] \right\} \quad (30)$$

and

$$\Delta u_{II_b} = \frac{H\theta^2\sqrt{r-r_2(s)}}{\pi\sqrt{s\theta}} \left\{ \frac{(s+r)(1+\theta)}{a} \left[\Pi\left(\frac{\pi}{2}, n, k\right) - \Pi(\phi, n, k) \right] - \left[F\left(\frac{\pi}{2}, k\right) - F(\phi, k) \right] \right\} \quad (31)$$

where

$$k = \sqrt{\frac{1-\theta}{4s\theta}} a_2 \quad a = (1+\theta)r - (1-\theta)s$$

$$\phi = \sin^{-1} \sqrt{\frac{a_1}{a_2}} \quad a_1 = (1+\theta)r_1(s) - (1-\theta)s$$

$$n = -\frac{a_2}{a} \quad a_2 = (1+\theta)r_2(s) - (1-\theta)s$$

Reentrant side edge.—A plan form has a reentrant edge if a line of constant y intersects the plan form at more than two points.

The load distribution in the region influenced by the reentrant side edge is to be determined for the wing (unshaded region) of figure 6. The side edge is first, for simplicity, the straight line $r=K_2s$, which is a subsonic trailing edge across which the Kutta condition is applied. The side edge then alternately becomes a subsonic leading and a subsonic trailing edge. The load distribution in region I is simply the Ackeret value $\Delta u_I = \frac{2\alpha U}{\beta}$, and $\Delta v_{I_a} = 0$. Regions II_a, II_b, and II_c are considered separately.

FIGURE 6.—Cancellation for obtaining loading in region influenced by reentrant side edge.

Region II_a:

From equation (24a) with $\Delta u_I = \frac{2\alpha U}{\beta}$,

$$\Delta u_{II_a} = \frac{\sqrt{r-K_2s}}{\pi} \int_{-s}^{K_2s} \frac{2\alpha U dr_o}{\beta(r-r_o)\sqrt{K_2s-r_o}} = \frac{4\alpha U}{\beta\pi} \tan^{-1} \sqrt{\frac{(K_2+1)s}{r-K_2s}} \quad (32a)$$

or, in x, y coordinates

$$\Delta u_{II_a} = \frac{4\alpha U}{\beta\pi} \tan^{-1} \sqrt{\frac{x+\beta y}{\beta(m_2x-y)}} \quad (32b)$$

Region II_b:

A knowledge of Δv_{I_b} is required. From equation (18b),

$$\Delta v_{I_b} = \frac{\partial}{\partial y} \left[\frac{4\alpha U}{\beta\pi} \int_{-\beta y}^{y/m_2} \tan^{-1} \sqrt{\frac{x_o+\beta y}{\beta(m_2x_o-y)}} dx_o + \frac{2\alpha U}{\beta} \int_{y/m_2}^x dx_o \right] = \frac{2\alpha U}{\sqrt{|\beta m_2|}} = 2\alpha U \sqrt{\frac{K_2+1}{K_2-1}} \quad (33)$$

The load distribution in region II_b is then, recalling that $\Delta v_{I_a} = 0$,

$$\begin{aligned} \Delta u_{II_b} &= \frac{\sqrt{r-r_2(s)}}{\pi} \int_{-s}^{r_2(s)} \frac{2\alpha U dr_o}{\beta(r-r_o)\sqrt{r_2(s)-r_o}} - \\ &\quad \frac{\left[1 - \frac{dr_2(s)}{ds}\right]}{2\beta\pi\sqrt{r-r_2(s)}} \left[\int_{-s}^s \frac{2\alpha U dr_o}{\sqrt{r_2(s)-r_o}} + \int_s^{r_2(s)} \left(2\alpha U - 2\alpha U \sqrt{\frac{K_2+1}{K_2-1}}\right) \frac{dr_o}{\sqrt{r_2(s)-r_o}} \right] \\ &= \frac{2\alpha U}{\beta\pi} \left(2 \tan^{-1} \sqrt{\frac{r_2(s)+s}{r-r_2(s)}} - \frac{\left[1 - \frac{dr_2(s)}{ds}\right]}{\sqrt{r-r_2(s)}} \left\{ \sqrt{r_2(s)+s} - \sqrt{\left(\frac{K_2+1}{K_2-1}\right) [r_2(s)-s]} \right\} \right) \end{aligned} \quad (34)$$

Region II_c:

Because the Kutta condition is applied,

$$\Delta u_{II_c} = \frac{4\alpha U}{\beta\pi} \tan^{-1} \sqrt{\frac{r_2(s)+s}{r-r_2(s)}} \quad (35)$$

TRAILING-EDGE CANCELLATION

The calculation of lift distributions on swept wings having subsonic trailing edges requires cancellation wings of the type shown in figure 7. These wings cancel that part of the lift of the basic triangular wing that is downstream of the trailing edge of the swept wing (references 3, 4, 6, and 7). The lift is specified in region I. The lift in regions II and III is to be determined subject to the conditions that $w=0$ and that the Kutta condition applies at $r=r_1(s)$ and $r=r_2(s)$.

The wing of figure 7 (a) differs from the previously discussed cases in that two unknown regions (II and III) are continuously interacting. A special treatment is required in order to obtain the loading in regions II and III. (See, for example, reference 6.) Approximate solutions can be obtained, however, using equations (24a) and (24b). For example, if the load at (r,s) in region II is desired, first assume that Δu_{III} is known. Then,

$$\Delta u_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \left[\int_{\frac{Mc_r}{2\beta}}^{r_1(s)} \frac{\Delta u_{III} dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} + \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \right] \quad (36)$$

An expression for Δu_{III} is, by integration along lines of constant r_o (fig. 7 (a)),

$$\Delta u_{III} = \frac{\sqrt{s-s_1(r_o)}}{\pi} \left[\int_{\frac{Mc_r}{2\beta}}^{s_2(r_o)} \frac{\Delta u_{II} ds_o}{(s-s_o)\sqrt{s_1(r_o)-s_o}} + \int_{s_2(r_o)}^{s_1(r_o)} \frac{\Delta u_I ds_o}{(s-s_o)\sqrt{s_1(r_o)-s_o}} \right]$$

An approximate expression for Δu_{III} is then

$$\Delta u_{III} \approx \frac{\sqrt{s-s_1(r_o)}}{\pi} \int_{s_2(r_o)}^{s_1(r_o)} \frac{\Delta u_I ds_o}{(s-s_o)\sqrt{s_1(r_o)-s_o}} \quad (37)$$

Equation (36), which may now be written in terms of Δu_I by substituting equation (37) for Δu_{III} , becomes

$$\Delta u_{II} \approx \frac{\sqrt{r-r_2(s)}}{\pi} \left\{ \int_{\frac{Mc_r}{2\beta}}^{r_1(s)} \frac{dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \left[\frac{\sqrt{s-s_1(r_o)}}{\pi} \int_{s_2(r_o)}^{s_1(r_o)} \frac{\Delta u_I ds_o}{(s-s_o)\sqrt{s_1(r_o)-s_o}} \right] + \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \right\} \quad (38)$$

The first term on the right side of equation (38) approximates the contribution of region III to the loading in region II. This term, as indicated in reference 6, is negligible for the commonly encountered Δu_I distributions (corresponding to steady lift, roll, or pitch) and $\frac{\beta dy_1(x)}{dx} > 0.5$. For those cases, equation (38) simplifies to

$$\Delta u_{II} \approx \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \quad (39)$$

The Kutta condition at $r=r_2(s)$ is satisfied by both equations

(38) and (39). Equation (39) can be reduced to elliptic integrals in canonical form by the substitution indicated in equation (29). The elliptic integrals may be avoided by expanding Δu_I in a Taylor's series about $r_o=r_2(s)$. Equation (39) can then be readily integrated, term by term, to yield a very good approximation for Δu_{II} in terms of algebraic and trigonometric functions.

When region I has a partly supersonic leading edge (fig. 7 (b)), it is possible to write exact expressions for the linearized load distribution in regions II and III. For example, the load at point (r,s) of figure 7 (b) is

$$\Delta u_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \left\{ \int_c^{r_1(s)} \frac{dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \left[\frac{\sqrt{s-s_1(r_o)}}{\pi} \int_{s_3(r_o)}^{s_1(r_o)} \frac{\Delta u_I ds_o}{(s-s_o)\sqrt{s_1(r_o)-s_o}} \right] + \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \right\} \quad (40)$$

APPENDIX A

SYMBOLS

The following symbols are used in this report:

a	$=$	$(1+\theta)r-(1-\theta)s$
a_1	$=$	$(1+\theta)r_1(s)-(1-\theta)s$
a_2	$=$	$(1+\theta)r_2(s)-(1-\theta)s$
ΔC_p		local lift coefficient, $\frac{p_B-p_T}{q}$
c		constant
c_r		root chord of swept wing
$E(\phi, k)$		elliptic integral of second kind, $E(\phi, k) = \int_0^{\sin \phi} \frac{\sqrt{1-k^2\omega_o^2}}{\sqrt{1-\omega_o^2}} d\omega_o$
$F(\phi, k)$		elliptic integral of first kind, $F(\phi, k) = \int_0^{\sin \phi} \frac{d\omega_o}{\sqrt{(1-\omega_o^2)(1-k^2\omega_o^2)}}$
$G(r, s_o)$		function of r and s_o defined by equation (12)
H	$=$	$\frac{2\alpha U}{\beta E\left(\frac{\pi}{2}, \sqrt{1-\theta^2}\right)}$
K		slope of plan-form edge in r, s coordinates, dr/ds
k		modulus of elliptic integrals
M		Mach number
m		slope of plan-form edge in x, y coordinates, dy/dx
n		parameter of elliptic integral of third kind
p		local static pressure
q	$=$	$\frac{1}{2} \rho U^2$
r, r_o		Mach coordinate system (equation (4))
s, s_o		
U		free-stream velocity
u, v, w		perturbation velocities in x -, y -, and z -directions, respectively
Δu	$=$	$u_T - u_B$ (proportional to local lift)
Δv	$=$	$v_T - v_B$
x, x_o		Cartesian coordinate system
y, y_o		
z, z_o		

α		angle of attack
β	$=$	$\sqrt{M^2-1}$
δ		semivertex angle of triangular wing
θ	$=$	$\beta \tan \delta$
$\Pi(\phi, n, k)$		elliptic integral of third kind, $\int_0^{\sin \phi} \frac{d\omega_o}{(1+n\omega_o^2)\sqrt{(1-k^2\omega_o^2)(1-\omega_o^2)}}$
ρ		density
τ		area of integration
ϕ		amplitude of elliptic integrals
φ		perturbation velocity potential
$\Delta\varphi$		doublet strength, $\varphi_T - \varphi_B$
ω_o		integration variable
Regions:		
I		region on cancellation wing for which loading is specified
$I_a, I_b, \dots$		subdivisions of region I
II		region on cancellation wing for which $w=0$
$II_a, II_b, \dots$		subdivisions of region II
III		additional region on cancellation wing for which $w=0$
Special designations:		
$r=r_1(s)$		r as function of s along plan-form boundary 1
$s=s_1(r)$		s as function of r along plan-form boundary 1
$y=y_1(x)$		y as function of x along plan-form boundary 1
$x=x_1(y)$		x as function of y along plan-form boundary 1
$r=r_2(s)$		r as function of s along plan-form boundary 2
$s=s_2(r)$		s as function of r along plan-form boundary 2 and so forth.
Subscripts:		
1, 2, 3		refers to plan-form boundaries 1, 2, and 3, respectively
I, II		refers to regions I and II, respectively
B		bottom surface of $z=0$ plane
T		top surface of $z=0$ plane
o		variable of integration

APPENDIX B

SOLUTION OF INTEGRAL EQUATIONS

Consider the following integral equation (in the notation of the appendix in reference 5), where the function $f(x)$ is assumed known and the function $u(\xi)$ is to be determined:

$$f(x) = \int_a^x \frac{u(\xi) d\xi}{(x-\xi)^{3/2}} = \int_a^x \frac{[u(\xi) - u(x)] d\xi}{(x-\xi)^{3/2}} - \frac{2u(x)}{(x-a)^{1/2}} \quad (B1)$$

After an integration by parts, equation (B1) may be written

$$-\frac{f(x)}{2} - \frac{u(a)}{(x-a)^{1/2}} = \int_a^x \frac{u'(\xi) d\xi}{(x-\xi)^{1/2}} \quad (B2)$$

Equation (B2) is now an integral equation of the Abel type. The continuous solution for $u(\xi)$ is (reference 14)

$$u(z) = -\frac{1}{2\pi} \int_a^z \frac{f(x) dx}{(z-x)^{1/2}} \quad (B3)$$

evaluated at $z=\xi$. This result is presented in reference 5.

Equation (11b) corresponds to equation (B1) with $u(\xi) = G(r, s_o)$ and $f(x) = 0$. The solution for $G(r, s_o)$, according to equation (B3), is then

$$G(r, s_o) = 0 \quad (13)$$

Equation (14) corresponds to equation (B1) with

$$\begin{aligned} \xi &= r_o & a &= r_2(s_o) \\ x &= r & f(x) &= -\int_{r_1(s_o)}^{r_2(s_o)} \frac{\Delta\varphi_1 dr_o}{(r-r_o)^{3/2}} \end{aligned}$$

$$u(\xi) = \Delta\varphi_{II}$$

The solution for $\Delta\varphi_{II}$ according to equation (B3) is then

$$\Delta\varphi_{II} = \frac{1}{2\pi} \int_{r_2(s)}^z \frac{dr}{\sqrt{z-r}} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)^{3/2}} \quad (B4)$$

Reversing the order of integration and integrating yield

$$\Delta\varphi_{II} = \frac{\sqrt{z-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(z-r_o)\sqrt{r_2(s)-r_o}} \quad (B5)$$

Equation (B5), evaluated at $z=r$ and $s_o=s$, yields

$$\Delta\varphi_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \quad (15)$$

The derivation of equation (15) is similar to that for equation (16) of reference 5.

APPENDIX C

DIFFERENTIATION TO OBTAIN Δu_{II}

The differentiation indicated in equation (16)

$$\frac{2\beta}{M} \Delta u_{II} = \left(\frac{\partial}{\partial r} + \frac{\partial}{\partial s} \right) \left[\frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \right] \quad (16)$$

is to be conducted.

First,

$$\begin{aligned} \frac{2\beta}{M} \Delta u_{II} = & \frac{1 - \frac{dr_2(s)}{ds}}{2\pi\sqrt{r-r_2(s)}} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} + \\ & \frac{\sqrt{r-r_2(s)}}{\pi} \left(\frac{\partial}{\partial r} + \frac{\partial}{\partial s} \right) \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \end{aligned} \quad (C1)$$

Inasmuch as $\Delta\varphi_I$ is a function of r_o and s ,

$$\frac{\partial}{\partial r} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} = - \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)^2\sqrt{r_2(s)-r_o}} \quad (C2a)$$

and

$$\begin{aligned} \frac{\partial}{\partial s} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} = & \int_{r_1(s)}^{r_2(s)} \frac{\left(\frac{\partial \Delta\varphi_I}{\partial s} \right) dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} + \\ \lim_{r \rightarrow r_2(s)} \left\{ -\frac{1}{2} \frac{dr_2(s)}{ds} \int_{r_1(s)}^{r_o} \frac{\Delta\varphi_I dr_o}{(r-r_o)[r_2(s)-r_o]^{3/2}} + \right. \\ \left. \frac{[(\Delta\varphi_I)_{r_o=r_2(s)}]}{(r-r_o)\sqrt{r_2(s)-r_o}} \frac{dr_2(s)}{ds} \right\} - & \frac{[(\Delta\varphi_I)_{r_o=r_1(s)}]}{[r-r_1(s)]\sqrt{r_2(s)-r_1(s)}} \frac{dr_1(s)}{ds} \end{aligned} \quad (C2b)$$

However, $[(\Delta\varphi_I)_{r_o=r_1(s)}] = 0$ and, by integration by parts,

$$\begin{aligned} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)[r_2(s)-r_o]^{3/2}} = & -2 \int_{r_1(s)}^{r_2(s)} \frac{\left[\frac{\partial \Delta\varphi_I}{\partial r_o} + \frac{\Delta\varphi_I}{(r-r_o)} \right] dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} + \\ & \lim_{r \rightarrow r_1(s)} \left\{ \frac{2\Delta\varphi_I}{(r-r_o)\sqrt{r_2(s)-r_o}} \right\}_{r_1(s)} \end{aligned}$$

so that equation (C2b) can be written as

$$\begin{aligned} \frac{\partial}{\partial s} \int_{r_1(s)}^{r_2(s)} \frac{\Delta\varphi_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} = & \int_{r_1(s)}^{r_2(s)} \frac{\frac{\partial \Delta\varphi_I}{\partial s} dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} + \\ \frac{dr_2(s)}{ds} \int_{r_1(s)}^{r_2(s)} \frac{\left[\frac{\partial \Delta\varphi_I}{\partial r_o} + \frac{\Delta\varphi_I}{(r-r_o)} \right] dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} \end{aligned} \quad (C3)$$

Equations (C2a) and (C3) are substituted into equation (C1) and the integrals containing $\Delta\varphi_I$ are integrated by parts, reducing equation (C1) to

$$\begin{aligned} \Delta u_{II} = & \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_o}{(r-r_o)\sqrt{r_2(s)-r_o}} - \\ & \frac{1 - \frac{dr_2(s)}{ds}}{2\beta\pi\sqrt{r-r_2(s)}} \int_{r_1(s)}^{r_2(s)} \frac{(\beta\Delta u_I - \Delta v_I) dr_o}{\sqrt{r_2(s)-r_o}} \end{aligned} \quad (17a)$$

APPENDIX D

ALTERNATIVE DERIVATION OF SOLUTION SATISFYING KUTTA CONDITION AT $r=r_2(s)$

The integral equation formulation in terms of $\Delta\varphi$ (equation (14)) resulted in a solution that was continuous in $\Delta\varphi$ (equation (15)) but discontinuous, in general, in the derivative $\frac{\partial \Delta\varphi}{\partial x} = \Delta u$ (equation (17a)) at $r=r_2(s)$. In order to obtain

a solution continuous in Δu , an integral equation may be formulated that is similar to equation (14) but in terms of Δu rather than $\Delta\varphi$. The inversion shown in appendix B should result in a solution that is continuous in Δu but discontinuous in the derivatives of Δu at $r=r_2(s)$.

Consider equation (10) for the w distribution in the $z=0$ plane. This equation will be differentiated with respect to x using a technique introduced in reference 15 (equations (1) to (3) therein). The expression for w at any point (r,s) is, from equation (10),

$$w = -\frac{M}{8\pi} \iint \frac{\Delta\varphi dr_o ds_o}{(s-s_o)^{3/2}(r-r_o)^{3/2}} \quad (D1)$$

where τ is the area abc in figure 9 (a). The wing is moved upstream a distance dx (fig. 9 (b)), keeping the coordinate system fixed in space. The expression for the upwash at (r,s) now becomes

$$w + \frac{\partial w}{\partial x} dx = -\frac{M}{8\pi} \left[\int \int_{\tau} \left(\Delta\varphi + \frac{\partial \Delta\varphi}{\partial x_0} dx \right) \frac{dr_0 ds_0}{(s-s_0)^{3/2}(r-r_0)^{3/2}} + \int \int_{\Delta\tau} \frac{\Delta\varphi dr_0 ds_0}{(s-s_0)^{3/2}(r-r_0)^{3/2}} \right] \quad (D2)$$

The second term on the right side of equation (D2) is zero because $\Delta\varphi=0$ along the leading edge. Subtraction of equation (D1) from equation (D2) then yields

$$\frac{\partial w}{\partial x} = -\frac{M}{8\pi} \int \int_{\tau} \frac{\Delta u dr_0 ds_0}{(s-s_0)^{3/2}(r-r_0)^{3/2}} \quad (D3)$$

For points in region II of a cancellation wing, $\frac{\partial w}{\partial x}=0$. Thus, for the wing of figure 3 (a),

$$0 = \int_0^s \frac{ds_0}{(s-s_0)^{3/2}} \int_{r_1(s_0)}^r \frac{\Delta u dr_0}{(r-r_0)^{3/2}} \quad (D4)$$

This equation is the same as equation (11a) except that Δu replaces $\Delta\varphi$. The inversion by Abel's integral equation for Δu_{II} in terms of Δu_I then gives (from equation (15))

$$\Delta u_{II} = \frac{\sqrt{r-r_2(s)}}{\pi} \int_{r_1(s)}^{r_2(s)} \frac{\Delta u_I dr_0}{(r-r_0)\sqrt{r_2(s)-r_0}} \quad (24a)$$

Inasmuch as the integral equations of reference 5 are formulated in terms of Δu and are inverted by means of Abel's integral equation, only solutions satisfying the Kutta condition will result therein.

REPORT 1005

ANALYTICAL DETERMINATION OF COUPLED BENDING-TORSION VIBRATIONS OF CANTILEVER BEAMS BY MEANS OF STATION FUNCTIONS¹

By ALEXANDER MENDELSON and SELWYN GENDLER

SUMMARY

A method based on the concept of Station Functions is presented for calculating the modes and the frequencies of non-uniform cantilever beams vibrating in torsion, bending, and coupled bending-torsion motion. The method combines some of the advantages of the Rayleigh-Ritz and Stodola methods, in that a continuous loading function for the beam is used, with the advantages of the influence-coefficient method, in that the continuous loading function is obtained in terms of the displacements at a finite number of stations along the beam.

The Station Functions were derived for a number of stations ranging from one to eight. The deflections were obtained in terms of the physical properties of the beam and Station Numbers, which are general in nature and which have been tabulated for easy reference. Examples were worked out in detail; comparisons were made with exact theoretical results. For a uniform cantilever beam with n stations, the first n modes and frequencies were in good agreement with the theoretically exact values. The effect of coupling between bending and torsion was shown to reduce the first natural frequency to a value below that which it would have if there were no coupling.

INTRODUCTION

The failure of turbine and compressor blades due to vibrations has led to an increased interest in the study of the vibrations of these blades and in the determination of the natural modes and frequencies. In such theoretical studies, it is usually assumed that the compressor or turbine blade acts as a cantilever beam. The calculation of the uncoupled modes of arbitrarily shaped cantilever beams has been extensively investigated (references 1 to 4), but little work has as yet been done on calculating the coupled modes of such beams. If the geometry of the beam is such that coupling exists, the coupled modes are the actual vibrational modes that must be calculated.

Four general methods are currently in use for calculating uncoupled modes and frequencies of nonuniform beams. These methods are the Rayleigh-Ritz or energy method (reference 1), the Stodola method (references 5 and 6), the influence-coefficient method (references 4 and 7), and the integral-equation method (references 8 and 9). For each of these methods, computational work can usually be carried out in several ways. For example, by the use of influence coefficients the modes and frequencies can be determined by

Mykelstad's iteration procedure (reference 7) or by matrix methods (reference 4).

Any one of these methods can be extended to the calculation of coupled bending-torsion modes. The Rayleigh-Ritz method usually requires that the uncoupled modes be determined before the coupled modes can be computed. In applying either the Rayleigh-Ritz or the Stodola method, great difficulty is encountered in accurately determining the higher modes, because the lower modes must first be "swept out" by the use of exact orthogonality conditions (reference 10); the process will otherwise always converge back to the lowest mode. The same difficulties are encountered in the integral-equation method.

The influence-coefficient method reduces the problem to one having a finite number of degrees of freedom. The beam is divided into n intervals and a concentrated loading is assumed at the center of gravity of each interval. The solution of the resultant determinantal equation gives the first n modes. The accuracy of the higher modes is, however, very poor; only the first third of the modes and the first half of the frequencies are obtained within the usual engineering accuracy. Carrying along so many useless modes greatly increases the labor involved.

A straightforward accurate method for determining the coupled bending-torsion modes and the frequencies of non-uniform cantilever beams, together with applications of this method, was developed at the NACA Lewis laboratory during 1949 and is presented herein. This method is based on the use of Station Functions as first discussed in reference 11. Incorporated in the method are the advantages of the continuous-function deflections of the Rayleigh-Ritz and Stodola methods together with the advantages of the finite number of degrees of freedom of the influence-coefficient method. When the method is applied to a uniform beam, the first n roots of the resultant determinantal equation are amply accurate for engineering purposes.

The final determinantal equation is solved herein by matrix-iteration methods (reference 4). Any other convenient method may, however, be used and no knowledge of matrix algebra is needed to carry out the calculations by the matrix method. The work can be done by an inexperienced computer, as the only operations necessary for determining each mode are cumulative multiplication and division. In addition, for the case in which the coupling coefficient remains constant along the beam, a simple quadratic

¹ Supersedes NACA TN 2185, "Analytical Determination of Coupled Bending-Torsion Vibrations of Cantilever Beams by Means of Station Functions" by Alexander Mendelson and Selwyn Gendler, 1950.

formula and a series of curves are presented for determining the first coupled mode in terms of the uncoupled modes. Examples are developed in detail and comparisons with exact theoretical results are included.

THEORY

In the usual influence-coefficient methods for solving dynamical problems, a continuous body having an infinite number of degrees of freedom is replaced by a body having a finite number of degrees of freedom. Two principal assumptions are then made that introduce inaccuracies into the solutions, particularly in the higher modes: (1) The resultant of the inertia loads of all the infinitesimal masses in a finite interval passes through the center of gravity of that interval; and (2) a concentrated load that is the resultant of a distributed load produces the same deflection as the distributed load. An attempt has been made to reduce the error due to the second of these assumptions by the use of weighting matrices (reference 12). Although the accuracy is thereby increased, the effect of the first assumption is still great enough to introduce serious errors (reference 11).

In order to eliminate these assumptions, Rauscher (reference 11) introduced the concept of Station Functions. Instead of assuming the inertia loads to be concentrated at the centers of gravity of the intervals, the inertia loads and, consequently, the deflections are assumed to be continuous functions along the beam. The values of these continuous deflection functions at the reference stations must equal the deflections of the reference stations. The loading on the beam is therefore a continuous function of the deflections of the reference stations. Inasmuch as the deflections of the reference stations can be computed from the loading on the beam, which in turn is available from the deflections, the deflections are therefore obtained as functions of themselves. This procedure gives n homogeneous equations in the n deflections of the reference stations. The resultant determinantal equation has n roots for the frequency; it will be shown that for a uniform beam all these roots are sufficiently accurate for engineering purposes if the deflection functions are properly chosen. (For coupled bending-torsion vibrations, $2n$ homogeneous equations and $2n$ roots are obtained for n stations.)

The deflection functions used must satisfy the boundary conditions of the problem and also the condition that, at any reference station, the value of the function must equal the deflection of the reference station. Although it is always possible to find directly a single function that will satisfy these conditions, it is more convenient to obtain different component functions at each station and to add all these component functions together to give the complete deflection function. Rauscher (reference 11) calls these component deflection functions Station Functions. For example, the complete torsional deflection function for the beam will have the following form:

$$\theta(z) = \sum_{j=1}^n f_j(z) \theta_j$$

where

z dimensionless distance along beam

$\theta(z)$ torsional deflection at distance z from root

θ_j torsional deflection at j^{th} station

$f_j(z)$ Station Function in torsion associated with j^{th} station
(All symbols are defined in appendix A.)

Each Station Function must satisfy the boundary conditions of the problem and the following additional conditions: (1) At the reference station with which it is associated, the Station Function equals the deflection of that reference station; and (2) at all other reference stations, the Station Function equals zero. The sum of all these Station Functions will then give the complete deflection function for the beam. The Station Functions and corresponding loading functions are derived in appendix B for torsional vibrations,

FIGURE 1.—Cantilever beam with n stations.

bending vibrations, and coupled bending-torsion vibrations of an arbitrary cantilever beam.

Torsional vibrations.—It is shown in appendix B that the torsional deflections of the reference stations for a beam divided into n intervals of length δ , as shown in figure 1, are given by the following system of equations:

$$\theta_i = \omega^2 \delta^2 \frac{I_0}{C_0} \sum_{j=1}^n \alpha_{ij} \theta_j \quad (1)$$

where

$$\alpha_{ij} = \sum_{k=1}^i \frac{1}{C_k} \left[I_k N_{jk} - (k-1) I_k M_{jk} + \sum_{r=k+1}^n I_r M_{jr} \right] \quad (2)$$

i and $j = 1, 2, \dots, n$

ω frequency of vibration

δ length of interval

I_0 mass moment of inertia per unit length about elastic axis at root section

I_k ratio of average mass moment of inertia per unit length of k^{th} interval to mass moment of inertia per unit length at root section

C_0 torsional stiffness of root section

C_k ratio of average torsional stiffness of k^{th} interval to torsional stiffness at root section

The Station Numbers N_{jk} and M_{jk} are functions only of the integers k, j , and n and are defined as

$$\left. \begin{aligned} N_{jk} &\equiv \int_{k-1}^k z f_j(z) dz \\ M_{jk} &\equiv \int_{k-1}^k f_j(z) dz \end{aligned} \right\} \quad (3)$$

where $f_j(z)$ represents the Station Functions derived in appendix B and is given by

$$f_j(z) = a_{1j} z + a_{2j} z^2 + \dots + a_{(n+1)j} z^{(n+1)} \quad (4)$$

The coefficients a_{ij} are determined in appendix B by satisfying the conditions on the Station Functions. The integrals in equations (3) are thus seen to be integrals of

simple polynomials and the limits of integration are integers. The Station Numbers N_{jk} and M_{jk} are therefore rational numbers, functions only of the integers n , k , and j . These numbers have been evaluated and are listed in tables I to VIII.

If the physical properties of the beam under consideration are known for each of the n intervals, C_k and I_k will be known. The Station Numbers N_{jk} and M_{jk} can be obtained from tables I to VIII. From equation (2), α_{ij} can then be easily calculated.

Equation (1) actually represents n homogeneous equations in the n unknown deflections θ_i . With $\frac{1}{\omega^2} \frac{C_0}{I_0 \delta^2} \equiv \lambda$, these equations can be written as follows:

$$\left. \begin{aligned} (\alpha_{11}-\lambda)\theta_1 + \alpha_{12}\theta_2 + \alpha_{13}\theta_3 + \dots + \alpha_{1n}\theta_n &= 0 \\ \alpha_{21}\theta_1 + (\alpha_{22}-\lambda)\theta_2 + \alpha_{23}\theta_3 + \dots + \alpha_{2n}\theta_n &= 0 \\ \alpha_{31}\theta_1 + \alpha_{32}\theta_2 + (\alpha_{33}-\lambda)\theta_3 + \dots + \alpha_{3n}\theta_n &= 0 \\ \dots & \\ \alpha_{n1}\theta_1 + \alpha_{n2}\theta_2 + \alpha_{n3}\theta_3 + \dots + (\alpha_{nn}-\lambda)\theta_n &= 0 \end{aligned} \right\} \cdot \quad (5)$$

For a nontrivial solution, the determinant of the coefficients must vanish and the characteristic equation becomes

$$\begin{vmatrix} \alpha_{11} - \lambda & \alpha_{12} & \alpha_{13} & \dots & \alpha_{1n} \\ \alpha_{21} & \alpha_{22} - \lambda & \alpha_{23} & \dots & \alpha_{2n} \\ \alpha_{31} & \alpha_{32} & \alpha_{33} - \lambda & \dots & \alpha_{3n} \\ \dots & \dots & \dots & \dots & \dots \\ \alpha_{n1} & \alpha_{n2} & \alpha_{n3} & \dots & \alpha_{nn} - \lambda \end{vmatrix} = 0 \quad (6)$$

$$\text{or} \quad |\lambda I - [\alpha_{ij}]| = 0 \quad (6a)$$

where I is the identity matrix, and $[\alpha_{ij}]$ is the dynamical matrix.

Equation (6) can be solved for the n values of λ by any method available. The method used herein was to obtain the values of λ as the latent roots of the matrix $[\alpha_{ij}]$, which is actually the dynamical matrix for the problem. The mode shapes are obtained at the same time.

Bending vibrations.—The bending deflections for the beam shown in figure 1 are given by the following system of equations (appendix B):

$$y_i = \omega^2 \delta^4 \frac{m_0}{B_0} \sum_{j=1}^n \beta_{ij} y_j \quad (7)$$

where

$$\beta_{ij} \equiv \sum_{k=1}^i \frac{1}{B_k} \left(m_k (iP'_{jk} - Q'_{jk}) + \sum_{r=k+1}^n m_r \left\{ \left(i - k + \frac{1}{2} \right) N'_{jr} + \left[\frac{k^3 - (k-1)^3}{3} - \frac{(2k-1)i}{2} \right] M'_{jr} \right\} \right) \quad (8)$$

$i \text{ and } j = 1, 2, \dots, n$

m_0 mass per unit length of beam at root section

m_k ratio of average mass per unit length of k^{th} interval to mass per unit length at root section

B_0 bending stiffness at root section

B_k ratio of average bending stiffness of k^{th} interval to bending stiffness at root section

The Station Numbers M'_{jk} , N'_{jk} , P'_{jk} , and Q'_{jk} are functions only of the integers k , j , and n and are defined by

$$\left. \begin{aligned} P'_{jk} &\equiv \int_{k-1}^k \left[\frac{z^2}{2} - (k-1)z + \frac{1}{2} (k-1)^2 \right] g_j(z) dz \\ Q'_{jk} &\equiv \int_{k-1}^k \left[\frac{z^3}{6} - \frac{1}{2} (k-1)^2 z + \frac{1}{3} (k-1)^3 \right] g_j(z) dz \\ M'_{jk} &\equiv \int_{k-1}^k g_j(z) dz \\ N'_{jk} &\equiv \int_{k-1}^k z g_j(z) dz \end{aligned} \right\} \quad (9)$$

The Station Functions $g_j(z)$ are derived in appendix B and are given by

$$g_j(z) = b_{2j}z^2 + b_{3j}z^3 + b_{4j}z^4 + \dots + b_{(n+3)j}z^{(n+3)} \quad (10)$$

The integrals in equations (9) are thus seen to be integrals of simple polynomials. The Station Numbers M'_{jk} , N'_{jk} , P'_{jk} , and Q'_{jk} are rational numbers, functions only of the integers j , k , and n . These numbers have been evaluated and are listed in tables I to VIII.

If the physical properties of the beam are known for each of the n intervals, m_k and B_k will be known. The Station Numbers M'_{jk} , N'_{jk} , P'_{jk} , and Q'_{jk} are obtained from tables I to VIII; β_{ij} can then easily be calculated by equation (8).

The determinantal equation is:

$$\begin{vmatrix} \beta_{11}-\lambda & \beta_{12} & \beta_{13} & \dots & \beta_{1n} \\ \beta_{21} & \beta_{22}-\lambda & \beta_{23} & \dots & \beta_{2n} \\ \beta_{31} & \beta_{32} & \beta_{33}-\lambda & \dots & \beta_{3n} \\ \dots & \dots & \dots & \dots & \dots \\ \beta_{n1} & \beta_{n2} & \beta_{n3} & \dots & \beta_{nn}-\lambda \end{vmatrix} = 0 \quad (11)$$

or

$$|\lambda I - [\beta_{ii}]| = 0 \quad (11a)$$

where

$$\lambda \equiv \frac{B_0}{m_0 \delta^4} \frac{1}{\omega^2}$$

The dynamical matrix is $[\beta_{ij}]$.

Coupled bending-torsion vibration.—The torsional and bending deflections due to coupled bending-torsion vibrations of a cantilever beam are given by (appendix B):

$$\left. \begin{aligned} \theta_i &= \omega^2 \frac{m_0}{B_0} \delta^4 \sum_{j=1}^n \left(\Gamma \alpha_{ij} \theta_j + \epsilon \Gamma \gamma_{ij} \frac{y_j}{r_0} \right) \\ \frac{y_i}{r_0} &= \omega^2 \frac{m_0}{B_0} \delta^4 \sum_{j=1}^n \left(\delta_{ij} \theta_j + \beta_{ij} \frac{y_j}{r_0} \right) \end{aligned} \right\} \quad (12)$$

where

$$\epsilon \equiv \frac{r_0^2}{r_{g0}^2}$$

$$\Gamma \equiv \frac{1}{\delta^2} \frac{I_0}{C_0} \frac{B_0}{m_0}$$

r_0 absolute magnitude of projection of distance from elastic axis to center of gravity on perpendicular to bending direction for root section

r_{z0} radius of gyration about elastic axis at root section

The quantities α_{ij} and β_{ij} are defined by equations (2) and (8). The quantities γ_{ij} and δ_{ij} are given by

$$\left. \begin{aligned} \gamma_{ij} &= \sum_{k=1}^i \frac{1}{C_k} \left[S_k N'_{jk} - (k-1) S_k M'_{jk} + \sum_{r=k+1}^n S_r M'_{jr} \right] \\ \delta_{ij} &= \sum_{k=1}^i \frac{1}{B_k} \left(S_k (i P_{jk} - Q_{jk}) + \sum_{r=k+1}^n S_r \left\{ \left(i - k + \frac{1}{2} \right) N_{jr} + \left[\frac{k^3 - (k-1)^3}{3} - \frac{(2k-1)i}{2} \right] M_{jr} \right\} \right) \end{aligned} \right\} \quad (13)$$

where

$$P_{jk} = \int_{k-1}^k \left[\frac{z^2}{2} - (k-1)z + \frac{1}{2} (k-1)^2 \right] f_j(z) dz$$

$$Q_{jk} = \int_{k-1}^k \left[\frac{z^3}{6} - \frac{1}{2} (k-1)^2 z + \frac{1}{3} (k-1)^3 \right] f_j(z) dz$$

and S_k is the ratio of the average static mass unbalance of the k^{th} interval to the static mass unbalance at the root section.

The Station Numbers P_{jk} and Q_{jk} are listed in tables I to VIII with the other Station Numbers. The determinantal equation becomes

$$\begin{vmatrix} \Gamma\alpha_{11} - \lambda & \Gamma\alpha_{12} & \dots & \Gamma\alpha_{1n} & \epsilon\Gamma\gamma_{11} & \epsilon\Gamma\gamma_{12} & \dots & \epsilon\Gamma\gamma_{1n} \\ \Gamma\alpha_{21} & \Gamma\alpha_{22} - \lambda & \dots & \Gamma\alpha_{2n} & \epsilon\Gamma\gamma_{21} & \epsilon\Gamma\gamma_{22} & \dots & \epsilon\Gamma\gamma_{2n} \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \Gamma\alpha_{n1} & \Gamma\alpha_{n2} & \dots & \Gamma\alpha_{nn} - \lambda & \epsilon\Gamma\gamma_{n1} & \epsilon\Gamma\gamma_{n2} & \dots & \epsilon\Gamma\gamma_{nn} \\ \delta_{11} & \delta_{12} & \dots & \delta_{1n} & \beta_{11} - \lambda & \beta_{12} & \dots & \beta_{1n} \\ \delta_{21} & \delta_{22} & \dots & \delta_{2n} & \beta_{21} & \beta_{22} - \lambda & \dots & \beta_{2n} \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \delta_{n1} & \delta_{n2} & \dots & \delta_{nn} & \beta_{n1} & \beta_{n2} & \dots & \beta_{nn} - \lambda \end{vmatrix} = 0 \quad (14)$$

or

$$|\lambda I - [\eta_{ij}]| = 0 \quad (14a)$$

where $[\eta_{ij}]$ is the dynamical matrix and I is the identity matrix.

The first n roots of equation (14) will give the first n coupled frequencies.

APPLICATIONS AND RESULTS

In applying the previously discussed method, it is necessary to determine for a given beam the elements α_{ij} , β_{ij} , γ_{ij} , and δ_{ij} of the dynamical matrices. These quantities will depend on the physical properties of the beam and on the number of stations chosen. If the physical properties of the beam are known, the quantities α_{ij} , β_{ij} , γ_{ij} , and δ_{ij} can be directly calculated from equations (2), (8), and (13). The numbers M_{jk} , N_{jk} , P_{jk} , Q_{jk} , M'_{jk} , N'_{jk} , P'_{jk} , and Q'_{jk} appearing in these equations depend on the number of stations n that are used and can be read directly from tables I to VIII for any given number of stations up to eight. Once these quantities have been calculated, equations (6), (11), or (14) can be solved for the frequencies by any method desired. The matrix-

iteration method used herein is simple and rapid and requires no particular computing skill. As will be indicated, however, the accuracy of equations (6), (11), and (14) is such that relatively few stations need be used, in which case it may be convenient to expand the determinants and to solve the resultant low-order algebraic equation.

In order to illustrate the accuracy, this method was applied to torsional vibrations, bending vibrations, and coupled vibrations of a uniform cantilever beam. The exact theoretical values for torsional vibrations and bending vibrations of uniform cantilevers are well known. The exact theoretical values for the coupled bending-torsion vibration of a uniform beam were calculated (appendix D). A comparison was then made between the values obtained by the method presented and the exact theoretical values. The number of stations used was 1, 2, and 3 ($n=1$, $n=2$, and $n=3$). The comparisons are summarized in table IX.

Torsional vibration.—For the case of a uniform beam, $C_k = I_k = 1$ and equation (2) becomes

$$\alpha_{ij} = \sum_{k=1}^i \left[N_{jk} - (k-1) M_{jk} + \sum_{r=k+1}^n M_{jr} \right] \quad (15)$$

The values of N_{jk} and M_{jk} are given in tables I to VIII. The table to be used depends on the choice of the number of stations.

Let $n=1$;

$$\therefore \alpha_{11} = N_{11}$$

From table I, $N_{11} = 5/12$,

$$\therefore \alpha_{11} = 5/12$$

and

$$\theta_1 = \frac{5}{12} l^2 \frac{I_0}{C_0} \omega^2 \theta_1$$

or

$$\omega^2 = \frac{12}{5} \frac{C_0}{I_0 l^2} = 2.400 \frac{C_0}{I_0 l^2}$$

$$\omega = 1.549 \sqrt{\frac{C_0}{I_0 l^2}}$$

The exact theoretical value for the first torsional frequency is

$$\omega = 1.571 \sqrt{\frac{C_0}{I_0 l^2}}$$

The percentage error is -1.4 when only one station is used.

The mode shape obtained by the method of Station Functions agrees well with the theoretical mode shape, as is shown in figure 2 (a).

Let $n=2$; then by equation (15) and table II,

$$\alpha_{11} = N_{11} + M_{12} = \frac{8}{15} + \frac{5}{12} = \frac{57}{60}$$

$$\alpha_{12} = N_{21} + M_{22} = -\frac{31}{240} + \frac{29}{48} = \frac{57}{120}$$

$$\alpha_{21} = N_{11} + N_{12} = \frac{8}{15} + \frac{8}{15} = \frac{16}{15}$$

$$\alpha_{22} = N_{21} + N_{22} = -\frac{31}{240} + \frac{239}{240} = \frac{13}{15}$$

FIGURE 2.—Comparison of theoretical mode shapes with mode shapes obtained by taking n stations along the beam for torsional vibrations.

The determinantal equation then becomes

$$\begin{vmatrix} \frac{57}{60} - \lambda & \frac{57}{120} \\ \frac{16}{15} & \frac{13}{15} - \lambda \end{vmatrix} = 0$$

which gives

$$\lambda_1 = 1.6214$$

$$\lambda_2 = 0.1953$$

Therefore

$$\omega_1 = 1.571 \sqrt{\frac{C_0}{I_0 l^2}}$$

$$\omega_2 = 4.526 \sqrt{\frac{C_0}{I_0 l^2}}$$

The exact theoretical values are

$$\omega_1 = 1.571 \sqrt{\frac{C_0}{I_0 l^2}}$$

$$\omega_2 = 4.712 \sqrt{\frac{C_0}{I_0 l^2}}$$

The percentage errors of the first two modes, for only two stations, are found to be 0 and -4.

The mode shapes are shown in figures 2 (b) and 2 (c). Agreement of the first mode with the exact theoretical shape is excellent; the second mode agrees fairly well.

Let $n=3$; then by equation (15) and table III,

$$\begin{aligned} \alpha_{11} &= N_{11} + M_{12} + M_{13} = 0.945833 \\ \alpha_{12} &= N_{21} + M_{22} + M_{23} = 0.958333 \\ \alpha_{13} &= N_{31} + M_{32} + M_{33} = 0.520834 \\ \alpha_{21} &= N_{11} + N_{12} + 2M_{13} = 1.033333 \\ \alpha_{22} &= N_{21} + N_{22} + 2M_{23} = 1.883333 \\ \alpha_{23} &= N_{31} + N_{32} + 2M_{33} = 1.011113 \\ \alpha_{31} &= N_{11} + N_{12} + N_{13} = 1.012500 \\ \alpha_{32} &= N_{21} + N_{22} + N_{23} = 2.025000 \\ \alpha_{33} &= N_{31} + N_{32} + N_{33} = 1.387501 \end{aligned}$$

The determinantal equation is

$$\begin{vmatrix} 0.945833 - \lambda & 0.958333 & 0.520834 \\ 1.033333 & 1.883333 - \lambda & 1.011113 \\ 1.012500 & 2.025000 & 1.387501 - \lambda \end{vmatrix} = 0$$

The solutions are

$$\lambda_1 = 3.6474$$

$$\lambda_2 = 0.4093$$

$$\lambda_3 = 0.1599$$

Therefore

$$\omega_1 = 1.571 \sqrt{\frac{C_0}{I_0 l^2}}$$

$$\omega_2 = 4.689 \sqrt{\frac{C_0}{I_0 l^2}}$$

$$\omega_3 = 7.502 \sqrt{\frac{C_0}{I_0 l^2}}$$

FIGURE 3.—Comparison of theoretical mode shapes with mode shapes obtained by taking n stations along the beam for bending vibrations.

The exact theoretical values are

$$\omega_1 = 1.571 \sqrt{\frac{C_0}{I_0 l^2}}$$

$$\omega_2 = 4.712 \sqrt{\frac{C_0}{I_0 l^2}}$$

$$\omega_3 = 7.854 \sqrt{\frac{C_0}{I_0 l^2}}$$

The percentage errors of the first three modes, calculated by use of three stations, are found to be 0, -0.5, and -4.5, respectively.

The mode shapes are shown in figures 2 (d) to 2 (f). The first two modes agree very well with the theoretical shapes; agreement of the third mode is fair.

This procedure can be carried out as shown for any number of stations desired.

Bending vibrations.—For a uniform beam, $B_k = m_k = 1$ and equation (8) becomes

$$\beta_{ij} = \sum_{k=1}^n \left\{ i P'_{jk} - Q'_{jk} + \sum_{r=k+1}^n \left[\left(i - k + \frac{1}{2} \right) N'_{jr} + \left(\frac{k^3 - (k-1)^3}{3} - \frac{(2k-1)}{2} i \right) M'_{jr} \right] \right\} \quad (16)$$

Let $n=1$;

$$\therefore \beta_{11} = P'_{11} - Q'_{11}$$

and from table I

$$\beta_{11} = \frac{71}{630} - \frac{31}{1008} = \frac{59}{720}$$

Therefore, from equation (7),

$$\omega = 3.493 \sqrt{\frac{B_0}{m_0 l^4}}$$

The exact theoretical value is

$$\omega = 3.516 \sqrt{\frac{B_0}{m_0 l^4}}$$

The percentage error for just one station is found to be -0.65:

The mode shape is shown in figure 3 (a) and is seen to agree very well with the theoretically exact shape.

Let $n=2$; then by equation (16) and table II,

$$\beta_{11} = P'_{11} - Q'_{11} + \frac{1}{2} N'_{12} - \frac{1}{6} M'_{12} = 0.422745$$

$$\beta_{12} = P'_{21} - Q'_{21} + \frac{1}{2} N'_{22} - \frac{1}{6} M'_{22} = 0.295925$$

$$\beta_{21} = 2P'_{11} + 2P'_{12} - Q'_{11} - Q'_{12} + \frac{3}{2} N'_{12} - \frac{2}{3} M'_{12} = 1.145167$$

$$\beta_{22} = 2P'_{21} + 2P'_{22} - Q'_{21} - Q'_{22} + \frac{3}{2} N'_{22} - \frac{2}{3} M'_{22} = 0.905530$$

The characteristic equation is

$$\begin{vmatrix} 0.422745 - \lambda & 0.295925 \\ 1.145167 & 0.905530 - \lambda \end{vmatrix} = 0$$

The roots are

$$\lambda_1 = 1.2943$$

$$\lambda_2 = 0.0339$$

$$\therefore \omega_1 = 3.516 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 21.71 \sqrt{\frac{B_0}{m_0 l^4}}$$

The exact theoretical values are

$$\omega_1 = 3.516 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 22.04 \sqrt{\frac{B_0}{m_0 l^4}}$$

The percentage errors for two stations are therefore found to be 0 for the first mode and -1.5 for the second mode. The mode shapes are plotted in figures 3 (b) and 3 (c). The first mode agrees excellently with the theoretically exact shape; the second mode agrees fairly well.

Let $n=3$; then by equation (16) and table III,

$$\beta_{11} = P'_{11} - Q'_{11} + \frac{1}{2} N'_{12} + \frac{1}{2} N'_{13} - \frac{1}{6} M'_{12} - \frac{1}{6} M'_{13} = 0.270604$$

$$\beta_{12} = P'_{21} - Q'_{21} + \frac{1}{2} N'_{22} + \frac{1}{2} N'_{23} - \frac{1}{6} M'_{22} - \frac{1}{6} M'_{23} = 1.009943$$

$$\beta_{13} = P'_{31} - Q'_{31} + \frac{1}{2} N'_{32} + \frac{1}{2} N'_{33} - \frac{1}{6} M'_{32} - \frac{1}{6} M'_{33} = 0.487441$$

$$\beta_{21} = 2P'_{11} + 2P'_{12} - Q'_{11} - Q'_{12} + \frac{3}{2} N'_{12} + 2N'_{13} - \frac{2}{3} M'_{12} - \frac{4}{3} M'_{13} = 0.648170$$

$$\beta_{22} = 2P'_{21} + 2P'_{22} - Q'_{21} - Q'_{22} + \frac{3}{2} N'_{22} + 2N'_{23} - \frac{2}{3} M'_{22} - \frac{4}{3} M'_{23} = 3.266250$$

$$\beta_{23} = 2P'_{31} + 2P'_{32} - Q'_{31} - Q'_{32} + \frac{3}{2} N'_{32} + 2N'_{33} - \frac{2}{3} M'_{32} - \frac{4}{3} M'_{33} = 1.689891$$

$$\beta_{31} = 3P'_{11} + 3P'_{12} + 3P'_{13} - Q'_{11} - Q'_{12} - Q'_{13} + \frac{5}{2} N'_{12} + 4N'_{13} - \frac{7}{6} M'_{12} - \frac{10}{3} M'_{13} = 0.985135$$

$$\beta_{32} = 3P'_{21} + 3P'_{22} + 3P'_{23} - Q'_{21} - Q'_{22} - Q'_{23} + \frac{5}{2} N'_{22} + 4N'_{23} - \frac{7}{6} M'_{22} - \frac{10}{3} M'_{23} = 5.822852$$

$$\beta_{33} = 3P'_{31} + 3P'_{32} + 3P'_{33} - Q'_{31} - Q'_{32} - Q'_{33} + \frac{5}{2} N'_{32} + 4N'_{33} - \frac{7}{6} M'_{32} - \frac{10}{3} M'_{33} = 3.204301$$

The characteristic equation is

$$\begin{vmatrix} 0.270604 - \lambda & 1.009943 & 0.487441 \\ 0.648170 & 3.266250 - \lambda & 1.689891 \\ 0.985135 & 5.822852 & 3.204301 - \lambda \end{vmatrix} = 0$$

The roots are

$$\lambda_1 = 6.5521$$

$$\lambda_2 = 0.1667$$

$$\lambda_3 = 0.0223$$

Therefore

$$\omega_1 = 3.516 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 22.04 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_3 = 60.20 \sqrt{\frac{B_0}{m_0 l^4}}$$

The exact values are

$$\omega_1 = 3.516 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 22.04 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_3 = 61.70 \sqrt{\frac{B_0}{m_0 l^4}}$$

The percentage errors for three stations are found to be 0, 0, and -2.4 , respectively. The modes are plotted in figures 3 (d) to 3 (f). The first two modes are seen to agree very well with the theoretical mode shape; agreement of the third mode is fair.

Coupled bending-torsion vibrations.—A uniform beam with the following constants was chosen:

$$\gamma = \frac{\omega_t^2}{\omega_b^2} = 38.56$$

$$\epsilon = 0.8$$

$$\Gamma = \frac{n^2}{193.2}$$

$$\epsilon\Gamma = \frac{n^2}{241.5}$$

The values of α_{ij} and β_{ij} are obtained as previously and are the same as given before for $n=1$, $n=2$, and $n=3$. Also, because $S_k = B_k = C_k = m_k = I_k = 1$, equations (13) become

$$\gamma_{ij} = \sum_{k=1}^i \left[N'_{jk} - (k-1)M'_{jk} + \sum_{r=k+1}^n M'_{jr} \right]$$

$$\delta_{ij} = \sum_{k=1}^i \left\{ i P_{jk} - Q_{jk} + \sum_{r=k+1}^n \left[\left(i - k + \frac{1}{2} \right) N_{jr} + \left(\frac{k^3 - (k-1)^3}{3} - \frac{2k-1}{2} i \right) M_{jr} \right] \right\}$$

Let $n=1$; then the determinant is

$$\begin{vmatrix} \Gamma\alpha_{11}-\lambda & \epsilon\Gamma\gamma_{11} \\ \delta_{11} & \beta_{11}-\lambda \end{vmatrix} = \begin{vmatrix} 0.002156-\lambda & 0.001196 \\ 0.111111 & 0.081944-\lambda \end{vmatrix} = 0$$

The roots are

$$\lambda_1 = 0.0837$$

$$\lambda_2 = 0.0005$$

$$\omega_1 = 3.46 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 44.7 \sqrt{\frac{B_0}{m_0 l^4}}$$

The procedure for calculating the exact theoretical values is derived in appendix D. The exact values are

$$\omega_1 = 3.49 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 20.6 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_3 = 49.1 \sqrt{\frac{B_0}{m_0 l^4}}$$

The percentage error for the first mode, calculated by use of one station, is -0.9 .

Let $n=2$; then the determinant is

$$\begin{vmatrix} \Gamma\alpha_{11}-\lambda & \Gamma\alpha_{12} & \epsilon\Gamma\gamma_{11} & \epsilon\Gamma\gamma_{12} \\ \Gamma\alpha_{21} & \Gamma\alpha_{22}-\lambda & \epsilon\Gamma\gamma_{21} & \epsilon\Gamma\gamma_{22} \\ \delta_{11} & \delta_{12} & \beta_{11}-\lambda & \beta_{12} \\ \delta_{21} & \delta_{22} & \beta_{21} & \beta_{22}-\lambda \end{vmatrix} = 0$$

Substituting the known values and solving for λ give for the first two roots

$$\lambda_1 = 1.3197$$

$$\lambda_2 = 0.0412$$

and the frequencies become

$$\omega_1 = 3.48 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 19.7 \sqrt{\frac{B_0}{m_0 l^4}}$$

The percentage errors for two stations are -0.3 for the first mode and -4.4 for the second mode.

This procedure can be carried out for any number of stations desired. For three stations, the frequencies obtained are

$$\omega_1 = 3.48 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_2 = 20.6 \sqrt{\frac{B_0}{m_0 l^4}}$$

$$\omega_3 = 48.2 \sqrt{\frac{B_0}{m_0 l^4}}$$

The percentage errors are -0.3 for the first mode, 0 for the second mode, and -1.8 for the third mode.

The results obtained by the method presented are seen to agree very well with the exact theoretical values.

These results are summarized in table IX, where a comparison is made with the results obtained for uncoupled bending and torsional vibrations by use of influence coefficients with weighted matrices (reference 12). The values using weighted matrices were taken from table I of reference 12. It can be seen that for a given number of stations, the results obtained by the method presented herein are considerably better than those obtained by using influence co-

FIGURE 4.—Variation of frequency ratio Ω with coupling coefficient ϵ for several values of uncoupled frequency ratio γ .

efficients with weighted matrices. In general, it is indicated that for a uniform cantilever beam using n stations along the beam, the first $n-1$ frequencies and modes are in excellent agreement with exact theoretical values and even the n^{th} mode is given within the accuracy with which the physical properties of the material are known. For a tapered beam, more stations may be required, depending on the amount of taper. The number of stations required to give satisfactory accuracy is listed in table X. A comparison is made by using weighted influence coefficients; the values are taken from table II of reference 12.

The first vibrational frequency is given approximately by equation (C2) (appendix C) when coupling exists between bending and torsion; it is plotted in figure 4. In order to check these curves, the exact solution was obtained (appen-

dix D) for the ratio $(\omega_t/\omega_b)^2$ equal to 4 and was plotted on the same figure. The values given by equation (C2) are seen to be in excellent agreement with the theoretically exact values.

The effect of the coupling between bending and torsion is to reduce the first natural frequency below that which would exist if there were no coupling. This effect is shown in figure 4, wherein the value of Ω is always less than 1. This decrease in the first natural frequency due to coupling is, however, relatively unimportant in the practical range of $(\omega_t/\omega_b)^2 > 4$ and $\epsilon < 0.75$.

SUMMARY OF RESULTS

A method based on the use of Station Functions is presented for calculating uncoupled and coupled bending-torsion modes and frequencies of arbitrary continuous cantilever beams. The results of calculations made by this method

indicated that by the use of Station Functions derived herein, n modes and frequencies can be obtained with sufficient accuracy by using just n stations along the beam if the beam is uniform. For a tapered beam, more stations may be required, depending on the amount of taper. The amount of computational labor is markedly less than for other methods. The use of Station Numbers tabulated herein further reduces the amount of calculation necessary. The effect of coupling between bending and torsion is shown to reduce the first natural frequency to a value below that which it would have if there were no coupling.

APPENDIX A

SYMBOLS

The following symbols are used in this report:

a_{ij}	coefficient in equation for Station Function in torsion	$q_b(z)$	bending loading function on beam
B	bending stiffness of beam, function of z	$q_t(z)$	torsional loading function on beam
B_0	bending stiffness at root section of beam	r	absolute magnitude of projection of distance from elastic axis to center of gravity on perpendicular to bending direction
B_k	ratio of average bending stiffness of k^{th} interval to bending stiffness of root section	r_{g0}	radius of gyration about elastic axis at root section
b_{ij}	coefficient in equation for Station Function in bending	r_0	absolute magnitude of projection of distance from elastic axis to center of gravity on perpendicular to bending direction for root section
C	torsional stiffness of beam, function of z	S	static mass unbalance, function of z , mr
C_0	torsional stiffness of root section of beam	S_0	static mass unbalance at root section, $m_0 r_0$
C_k	ratio of average torsional stiffness of k^{th} interval to torsional stiffness at root section	S_k	ratio of average of static mass unbalance at k^{th} section to static mass unbalance at root section
c_1, c_2, c_3	constants defined in appendix B	x	distance from root of beam, except where otherwise defined
$f_j(z)$	Station Function in torsion for j^{th} station (defined in text)	y	bending deflection, function of z
$g_j(z)$	Station Function in bending for j^{th} station (defined in text)	y_i	bending deflection at i^{th} station
I	mass moment of inertia per unit length of beam about elastic axis, function of z , except where otherwise defined	z	dimensionless distance along beam, x/δ
I_0	mass moment of inertia per unit length of beam about elastic axis at root section	$\alpha_{ij}, \beta_{ij}, \gamma_{ij}, \delta_{ij}, \eta_{ij}$	elements of dynamical matrix defined in text
I_k	ratio of average mass moment of inertia per unit length of k^{th} interval to mass moment of inertia per unit length at root section	Γ	$\frac{1}{\delta^2} \frac{I_0}{C_0} \frac{B_0}{m_0}$
i, j, k, n	station indices	γ	uncoupled frequency ratio, $(\omega_i/\omega_b)^2$
j, k, r	summation indices	δ	length of interval along beam between two stations
l	length of beam	ϵ	coupling coefficient, $(r_0/r_{g0})^2$
M_{jk}, N_{jk}, P_{jk}	Station Numbers (defined in text); function of indices j, k , and n	θ	torsional deflection, function of z
$Q_{jk}, M'_{jk}, N'_{jk}, P'_{jk}, Q'_{jk}$	of indices j, k , and n	θ_i	torsional deflection at i^{th} station
m	mass per unit length of beam, function of z	λ	root of frequency equation or characteristic root of dynamical matrix
m_0	mass per unit length of beam at root section	Ω	frequency ratio, $(\omega/\omega_b)^2$
m_k	ratio of average mass per unit length of k^{th} interval to mass per unit length at root section	ω	frequency of vibration
n	number of stations along beam	ω_b	frequency of uncoupled fundamental bending mode
		ω_t	frequency of uncoupled fundamental torsional mode
		$\ddot{}$	second derivative of deflection with respect to time

APPENDIX B

STATION FUNCTIONS AND DETERMINANTAL EQUATIONS

TORSIONAL VIBRATIONS

A schematic diagram of a cantilever beam divided into n intervals of length δ is shown in figure 1. The Station Functions for the torsional vibrations of such a beam must satisfy the following conditions:

At

$$z=0 \quad f_i(0)=0 \quad (B1)$$

$$z=n \quad f'_i(n)=0 \quad (B2)$$

$$z=i \quad f_i(i)=1 \quad (B3)$$

$$z=j \quad f_i(j)=0 \quad j \neq i \quad (B4)$$

where $f'(z)$ denotes the derivative with respect to z .

Equations (B1) and (B2) represent the boundary conditions that must be satisfied by a cantilever beam vibrating in torsion; equations (B3) and (B4) represent the further conditions imposed upon the Station Functions. These conditions will be satisfied by a function of the type

$$f_i(z) = a_{1i}z + a_{2i}z^2 + \dots + a_{(n+1)i}z^{(n+1)} \quad (B5)$$

where the coefficients a_{ij} must satisfy the following simultaneous equations obtained from conditions (B2), (B3), and (B4):

$$0 = a_{1i} + 2na_{2i} + 3n^2a_{3i} + \dots + (n+1)n^na_{(n+1)i} \quad (B2a)$$

$$1 = ia_{1i} + i^2a_{2i} + i^3a_{3i} + \dots + i^{(n+1)}a_{(n+1)i} \quad (B3a)$$

$$0 = ja_{1i} + j^2a_{2i} + j^3a_{3i} + \dots + j^{(n+1)}a_{(n+1)i} \quad j \neq i \quad (B4a)$$

The coefficients a_{ij} can be obtained by solving equations (B2a) to (B4a) and the functions $f_i(z)$ determined for each station. Equation (B5), however, can also be written in the following form:

$$f_i(z) = \frac{\prod_{j \neq i} (z-j)z(z-c_1)}{\prod_{j \neq i} (i-j)i(i-c_1)} \quad (B5a)$$

where Π represents the product for all values of j except $j=i$. The function in equation (B5a) obviously satisfies conditions (B1), (B3), and (B4) because it has zeros at all points specified by equation (B4), it equals 1 at the point specified by equation (B3), and it equals zero at the point specified by equation (B1). In order to satisfy condition (B2), the constant c_1 is determined by substitution of equation (B5a) into equation (B2).

$$c_1 = n \text{ for } i \neq n$$

$$c_1 = n \left(1 + \frac{1}{1 + \sum_{j \neq n} \frac{n}{n-j}} \right) \text{ for } i = n$$

Equation (B5) can be obtained from equation (B5a) by carrying out the indicated multiplications. The complete deflection function is then given by

$$\begin{aligned} \theta(z) &= f_1(z)\theta_1 + f_2(z)\theta_2 + \dots + f_n(z)\theta_n \\ &= \sum_{j=1}^n f_j(z)\theta_j \end{aligned} \quad (B6)$$

The continuous loading function $q_i(z)$ can now be written as

$$q_i(x) = I\omega^2\theta(z) = I\omega^2 \sum_{j=1}^n f_j(z)\theta_j \quad (B7)$$

A continuous loading function, which is a function of the deflections at the reference stations, has thus been obtained.

BENDING VIBRATIONS

The Station Functions for the bending vibrations of the beam shown in figure 1 must satisfy the following conditions: at

$$z=0 \quad g_i(0)=0 \quad (B8)$$

$$z=0 \quad g'_i(0)=0 \quad (B9)$$

$$z=n \quad g''_i(n)=0 \quad (B10)$$

$$z=n \quad g'''_i(n)=0 \quad (B11)$$

$$z=i \quad g_i(i)=1 \quad (B12)$$

$$z=j \quad g_i(j)=0 \quad j \neq i \quad (B13)$$

where $g'(z)$, $g''(z)$, and $g'''(z)$ denote the first, second, and third derivatives, respectively, of $g(z)$ with respect to z .

Equations (B8) to (B11) represent the boundary conditions that must be satisfied by a cantilever beam vibrating in bending and equations (B12) and (B13) represent the additional conditions imposed upon the Station Functions.

These conditions will be satisfied by functions of the type

$$g_i(z) = b_{2i}z^2 + b_{3i}z^3 + \dots + b_{(n+3)i}z^{(n+3)} \quad (B14)$$

where the coefficients b_{ij} must satisfy the following equations obtained from conditions (B10) to (B13):

$$0 = 2b_{2i} + 6nb_{3i} + \dots + (n+3)(n+2)n^{(n+1)}b_{(n+3)i} \quad (B10a)$$

$$0 = 6b_{3i} + 24nb_{4i} + \dots + (n+3)(n+2)(n+1)n^nb_{(n+3)i} \quad (B11a)$$

$$1 = i^2b_{2i} + i^3b_{3i} + \dots + i^{(n+3)}b_{(n+3)i} \quad (B12a)$$

$$0 = j^2b_{2i} + j^3b_{3i} + \dots + j^{(n+3)}b_{(n+3)i} \quad j \neq i \quad (B13a)$$

The coefficients can therefore be obtained from equations (B10a) to (B13a) and the functions $g_i(z)$ determined for

each station i . Equation (B14) can, however, be written in the following form:

$$g_i(z) = \frac{\prod_{j \neq i} (z-j) z^2 (z^2 + c_2 z + c_3)}{\prod_{j \neq i} (i-j) i^2 (i^2 + c_2 i + c_3)} \quad (\text{B14a})$$

where Π represents the product for all values of j except $j=i$. The function in equation (B14a) obviously satisfies conditions (B8), (B9), (B12), and (B13), because it has zeros at all points specified by conditions (B8), (B9), and (B13) and equals 1 at the point specified by equation (B12). In order to satisfy conditions (B10) and (B11), the constants c_2 and c_3 are determined by substitution of equation (B14a) into equations (B10) and (B11). The general forms for c_2 and c_3 are, however, complicated and it is easier to obtain the numerical values of these constants for each specific case. Equation (B14) can then be obtained from equation (B14a) by carrying out the indicated multiplications. The complete deflection function is then given by

$$y(z) = \sum_{j=1}^n g_j(z) y_j \quad (\text{B15})$$

The continuous bending loading function $q_b(z)$ can now be written as

$$q_b(z) = m \omega^2 y(z) = m \omega^2 \sum_{j=1}^n g_j(z) y_j \quad (\text{B16})$$

COUPLED BENDING-TORSION VIBRATIONS

The Station Functions for the coupled bending-torsion vibrations are the same as previously given for the bending vibrations and the torsion vibrations. The loading functions, however, are given as follows (reference 7):

$$\begin{aligned} q_i(z) &= I \omega^2 \theta(z) + S \omega^2 y(z) \\ &= \omega^2 \sum_{j=1}^n [I f_j(z) \theta_j + S g_j(z) y_j] \end{aligned} \quad (\text{B17})$$

and

$$\begin{aligned} q_b(z) &= S \omega^2 \theta(z) + m \omega^2 y(z) \\ &= \omega^2 \sum_{j=1}^n [S f_j(z) \theta_j + m g_j(z) y_j] \end{aligned} \quad (\text{B18})$$

DETERMINANTAL EQUATIONS AND DYNAMICAL MATRICES

Once the Station Functions and the corresponding loading functions have been determined, the deflections at the reference stations can be obtained in terms of the loading function. A homogeneous equation in the reference-station deflections for each station is thereby obtained. The determinant of the coefficients of the resultant set of homogeneous equations can be set equal to zero; the determinantal frequency equation is thus derived. The deflections at the reference stations are obtained by the well-known equations for obtaining influence coefficients.

Torsion.—The deflection at the station i due to the continuous loading $q_i(z)$ on the beam is given by

$$\theta_i = \delta^2 \int_0^i q_i(z) \int_0^z \frac{dz_1}{C} dz + \delta^2 \int_i^n q_i(z) \int_0^i \frac{dz_1}{C} dz \quad (\text{B19})$$

If C is assumed to have a constant value for each interval, these integrals may be written as the sum of integrals over each section. Equation (B19) then becomes

$$\theta_i = \frac{\delta^2}{C_0} \sum_{k=1}^i \frac{1}{C_k} \left[\int_{k-1}^k z q_i(z) dz + \int_{k-1}^k (1-k) q_i(z) dz + \int_k^n q_i(z) dz \right] \quad (\text{B20})$$

By substituting the relation

$$q_i(z) = \omega^2 I \sum_{j=1}^n f_j(z) \theta_j$$

and by assuming a constant value for I for each interval and changing the summation order,

$$\theta_i = \omega^2 \delta^2 \frac{I_0}{C_0} \sum_{j=1}^n \left\{ \sum_{k=1}^i \frac{1}{C_k} \left[I_k \int_{k-1}^k z f_j(z) dz - (k-1) I_k \int_{k-1}^k f_j(z) dz + \sum_{r=k+1}^n I_r \int_{r-1}^r f_j(z) dz \right] \right\} \theta_j \quad (\text{B21})$$

Let

$$\left. \begin{aligned} \int_{k-1}^k z f_j(z) dz &\equiv N_{jk} \\ \int_{k-1}^k f_j(z) dz &\equiv M_{jk} \end{aligned} \right\} \quad (\text{B22})$$

Then

$$\theta_i = \omega^2 \frac{I_0}{C_0} \delta^2 \sum_{j=1}^n \alpha_{ij} \theta_j \quad (\text{B23})$$

where

$$\alpha_{ij} \equiv \sum_{k=1}^i \frac{1}{C_k} \left[I_k N_{jk} - (k-1) I_k M_{jk} + \sum_{r=k+1}^n I_r M_{jr} \right] \quad (\text{B24})$$

If $C_k = I_k = 1$ (constant cross section), then

$$\alpha_{ij} = \sum_{k=1}^i \left[N_{jk} - (k-1) M_{jk} + \sum_{r=k+1}^n M_{jr} \right] \quad (\text{B25})$$

Let

$$\lambda \equiv \frac{C_0}{I_0 \omega^2 \delta^2} \quad (\text{B26})$$

Then

$$\lambda \theta_i = \sum_{j=1}^n \alpha_{ij} \theta_j \quad (\text{B23a})$$

and the characteristic equation is

$$|[\alpha_{ij}] - \lambda I| = 0 \quad (\text{B27})$$

where I is the identity matrix.

Bending.—The deflection at the station i due to the continuous loading $q_b(z)$ on the beam will be given by

$$\begin{aligned} y_i &= \delta^4 \int_0^i q_b(z) \int_0^z \frac{(z-z_1)(i-z_1)}{B} dz_1 dz + \\ &\quad \delta^4 \int_i^n q_b(z) \int_0^i \frac{(z-z_1)(i-z_1)}{B} dz_1 dz \end{aligned} \quad (\text{B28})$$

If B is assumed to have a constant value for each interval, these integrals may be written as the sum of integrals over each interval. Equation (B28) then becomes

$$y_i = \frac{\delta^4}{B_0} \sum_{k=1}^i \frac{1}{B_k} \left\{ i \int_{k-1}^k \left[\frac{z^2}{2} - (k-1)z + \frac{1}{2} (k-1)^2 \right] q_b(z) dz - \int_{k-1}^k \left[\frac{z^3}{6} - \frac{1}{2} (k-1)^2 z + \frac{1}{3} (k-1)^3 \right] q_b(z) dz + i \int_k^n \left[z - \frac{1}{2} (2k-1) \right] q_b(z) dz + \int_k^n \left[\frac{1}{2} (2k-1)z - \frac{k^3 - (k-1)^3}{3} \right] q_b(z) dz \right\} \quad (\text{B29})$$

By substituting the relation

$$q_b(z) = \omega^2 m \sum_{j=1}^n g_j(z) y_j \quad (\text{B30})$$

and by assuming a constant average value for m in each interval and changing the summation order,

$$y_i = \frac{\omega^2 m_0 \delta^4}{B_0} \sum_{j=1}^n \beta_{ij} y_j \quad (\text{B31})$$

where

$$\beta_{ij} = \sum_{k=1}^i \frac{1}{B_k} \left\{ m_k (i P'_{jk} - Q'_{jk}) + \sum_{r=k+1}^n m_r \left[\left(i - k + \frac{1}{2} \right) N'_{jr} + \left(\frac{k^3 - (k-1)^3}{3} - \frac{(2k-1)}{2} i \right) M'_{jr} \right] \right\} \quad (\text{B32})$$

$$\left. \begin{aligned} P'_{jk} &\equiv \int_{k-1}^k \left[\frac{z^2}{2} - (k-1)z + \frac{1}{2} (k-1)^2 \right] g_j(z) dz \\ Q'_{jk} &\equiv \int_{k-1}^k \left[\frac{z^3}{6} - \frac{1}{2} (k-1)^2 z + \frac{1}{3} (k-1)^3 \right] g_j(z) dz \\ N'_{jk} &\equiv \int_{k-1}^k z g_j(z) dz \\ M'_{jk} &\equiv \int_{k-1}^k g_j(z) dz \end{aligned} \right\} \quad (\text{B33})$$

For a uniform beam, $m_k = B_k = 1$ and equation (B32) becomes

$$\beta_{ij} = \sum_{k=1}^i \left(i P'_{jk} - Q'_{jk} + \sum_{r=k+1}^n \left\{ \left(i - k + \frac{1}{2} \right) N'_{jr} + \left[\frac{k^3 - (k-1)^3}{3} - \frac{(2k-1)}{2} i \right] M'_{jr} \right\} \right) \quad (\text{B32a})$$

Let

$$\lambda \equiv \frac{B_0}{\omega^2 \delta^4 m_0} \quad (\text{B34})$$

then the characteristic equation becomes

$$|[\beta_{ij}] - \lambda I| = 0 \quad (\text{B35})$$

where I is the identity matrix and β_{ij} is the dynamical matrix. In expanded form, equation (B35) becomes

$$\begin{vmatrix} \beta_{11} - \lambda & \beta_{12} & \dots & \beta_{1n} \\ \beta_{21} & \beta_{22} - \lambda & \dots & \beta_{2n} \\ \dots & \dots & \dots & \dots \\ \beta_{n1} & \beta_{n2} & \dots & \beta_{nn} - \lambda \end{vmatrix} = 0 \quad (\text{B35a})$$

where λ is a latent root of the matrix $[\beta_{ij}]$.

Coupled bending-torsion vibrations.—The deflections at station i are given as before by equations (B19) and (B28). The loading functions q_t and q_b are changed as follows:

$$\left. \begin{aligned} q_t(z) &= \omega^2 [I \theta(z) + S y(z)] \\ q_b(z) &= \omega^2 [S \theta(z) + m y(z)] \end{aligned} \right\} \quad (\text{B36})$$

If these two equations are substituted into equations (B19) and (B28) and the integrations are performed as previously, the following relation is obtained:

$$\left. \begin{aligned} \theta_i &= \frac{\omega^2 m_0 \delta^4}{B_0} \sum_{j=1}^n \left(\Gamma \alpha_{ij} \theta_j + \epsilon \Gamma \gamma_{ij} \frac{y_j}{r_0} \right) \\ \frac{y_i}{r_0} &= \frac{\omega^2 m_0 \delta^4}{B_0} \sum_{j=1}^n \left(\delta_{ij} \theta_j + \beta_{ij} \frac{y_j}{r_0} \right) \end{aligned} \right\} \quad (\text{B37})$$

where α_{ij} and β_{ij} are given in equations (B24) and (B32) and

$$\epsilon \equiv \frac{r_0^2}{r_{g0}^2}$$

$$\Gamma \equiv \frac{1}{\delta^2} \frac{I_0 B_0}{C_0 m_0}$$

$$\gamma_{ij} \equiv \sum_{k=1}^i \frac{1}{C_k} \left[S_k N'_{jk} - (k-1) S_k M'_{jk} + \sum_{r=k+1}^n S_r M'_{jr} \right]$$

$$\delta_{ij} \equiv \sum_{k=1}^i \frac{1}{B_k} \left\{ S_k [i P_{jk} - Q_{jk}] + \sum_{r=k+1}^n S_r \left[\left(i - k + \frac{1}{2} \right) N_{jr} + \left(\frac{k^3 - (k-1)^3}{3} - \frac{2k-1}{2} i \right) M_{jr} \right] \right\} \quad (\text{B38})$$

where

$$P_{jk} \equiv \int_{k-1}^k \left[\frac{z^2}{2} - (k-1)z + \frac{1}{2} (k-1)^2 \right] f_j(z) dz$$

$$Q_{jk} \equiv \int_{k-1}^k \left[\frac{z^3}{6} - \frac{1}{2} (k-1)^2 z + \frac{1}{3} (k-1)^3 \right] f_j(z) dz$$

the determinantal equation therefore is

$$|\lambda I - [\eta_{ij}]| = 0$$

where $[\eta_{ij}]$ is the dynamical matrix, the elements of which are as indicated in equation (B37). The matrix $[\eta_{ij}]$ is seen to be a $2n \times 2n$ matrix.

APPENDIX C

QUADRATIC FORMULA FOR FIRST COUPLED MODE

If only the first vibrational mode is desired, it is possible to obtain this mode approximately by coupling together the fundamental uncoupled bending mode with the fundamental uncoupled torsional mode to obtain a simple quadratic equation for the first coupled frequency. This equation is valid when the coupling coefficient ϵ is constant along the beam. The differential equations obtained by coupling the fundamental uncoupled torsional mode with the fundamental uncoupled bending mode are:

$$\left. \begin{aligned} m\ddot{y} + S\ddot{\theta} + m\omega_b^2 y &= 0 \\ S\ddot{y} + I\ddot{\theta} + I\omega_t^2 \theta &= 0 \end{aligned} \right\} \quad (C1)$$

where

m mass per unit length of beam, function of z
 S static mass unbalance, function of z

I mass moment of inertia about elastic axis, function of z
 ω_b frequency of uncoupled fundamental bending mode
 ω_t frequency of uncoupled fundamental torsional mode
 $\dots$ denotes differentiation twice with respect to time

These equations lead to a quadratic equation in the frequency ratio Ω , whose solution for the lowest frequency, provided ϵ is constant along the beam, is

$$\Omega \equiv \frac{\omega^2}{\omega_b^2} = \frac{1-\gamma}{2(1-\epsilon)} \left[1 - \sqrt{1 - \frac{4\gamma(1-\epsilon)}{(1-\gamma)^2}} \right] \quad (C2)$$

where

Ω frequency ratio, $(\omega/\omega_b)^2$
 γ uncoupled frequency ratio, $(\omega_t/\omega_b)^2$
 ϵ coupling coefficient, $(r/r_g)^2$

This quadratic has been plotted in figure 4 for values of ϵ ranging from 0 to 1 and values of $\gamma = (\omega_t/\omega_b)^2$ from 1 to 100.

APPENDIX D

EXACT SOLUTION FOR COUPLED BENDING-TORSION VIBRATIONS OF UNIFORM CANTILEVER BEAM

The differential equations for the equilibrium of an element of a beam vibrating in coupled bending-torsion vibrations can be put in the following dimensionless form:

$$\left. \begin{aligned} \frac{d^4 Y_1}{dx^4} &= \frac{ml^4}{B} \omega^2 Y_1 + \frac{ml^4}{B} \omega^2 Y_2 \\ \frac{d^2 Y_2}{dx^2} &= -\epsilon \frac{Il^2}{C} \omega^2 Y_1 - \frac{Il^2}{C} \omega^2 Y_2 \end{aligned} \right\} \quad (D1)$$

where

$$Y_1 \equiv y/r$$

$$Y_2 \equiv \theta$$

$$x \equiv \frac{\text{distance from root}}{l}$$

$$\epsilon = (r/r_g)^2$$

Now

$$\omega_b^2 = \frac{c_4 B}{ml^4}$$

$$\omega_t^2 = c_5 \frac{C}{Il^2}$$

where

$$c_4 = 12.36$$

$$c_5 = 2.467$$

Equations (D1) become

$$\left. \begin{aligned} \frac{d^4 Y_1}{dx^4} &= c_4 \Omega (Y_1 + Y_2) \\ \frac{d^2 Y_2}{dx^2} &= -\epsilon \frac{c_5 \Omega}{\gamma} Y_1 - \frac{c_5 \Omega}{\gamma} Y_2 \end{aligned} \right\} \quad (D2)$$

where

$$\Omega \equiv (\omega/\omega_b)^2$$

$$\gamma \equiv (\omega_t/\omega_b)^2$$

Let

$$\frac{dY_1}{dx} = Y_3$$

$$\frac{dY_3}{dx} = Y_4$$

$$\frac{dY_4}{dx} = Y_5$$

$$\frac{dY_2}{dx} = Y_6$$

$$\frac{dY_5}{dx} = c_4 \Omega (Y_1 + Y_2)$$

$$\frac{dY_6}{dx} = -\frac{c_5 \Omega}{\gamma} (\epsilon Y_1 + Y_2)$$

(D3)

Then

Equation (D3) can be written as the single matrix equation

$$\frac{d}{dx} \begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \\ Y_5 \\ Y_6 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ c_4 \Omega & c_4 \Omega & 0 & 0 & 0 & 0 \\ -\frac{\epsilon c_5 \Omega}{\gamma} & -\frac{c_5 \Omega}{\gamma} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \\ Y_5 \\ Y_6 \end{bmatrix} \quad (D4)$$

or

$$\frac{dY}{dx} = AY \quad (D4a)$$

where Y and A are the matrices indicated.

The solution to the matrix equation (D4) is given by

$$Y = e^{Ax} Y_0 \quad (D5)$$

where Y_0 is a column of arbitrary constants.

From the boundary conditions

$$\begin{aligned} \text{at } x=0 \quad Y_1 = Y_2 = Y_3 = 0 \\ x=1 \quad Y_4 = Y_5 = Y_6 = 0 \end{aligned}$$

$$Y_0 = Y(0) = \begin{bmatrix} 0 \\ 0 \\ 0 \\ Y_4(0) \\ Y_5(0) \\ Y_6(0) \end{bmatrix}$$

If then Ω_{ij} is an element of the matrizant e^A , the boundary conditions give

$$\begin{vmatrix} \Omega_{44} & \Omega_{45} & \Omega_{46} \\ \Omega_{54} & \Omega_{55} & \Omega_{56} \\ \Omega_{64} & \Omega_{65} & \Omega_{66} \end{vmatrix} = 0 \quad (D6)$$

Equation (D6) is the frequency equation. It has an infinite number of roots for ω .In order to determine the elements Ω_{ij} , e^A must be evaluated. Use will be made of Sylvester's theorem (reference 13).The λ matrix of A is

$$\begin{bmatrix} -\lambda & 0 & 1 & 0 & 0 & 0 \\ 0 & -\lambda & 0 & 0 & 0 & 1 \\ 0 & 0 & -\lambda & 1 & 0 & 0 \\ 0 & 0 & 0 & -\lambda & 1 & 0 \\ c_4\Omega & c_4\Omega & 0 & 0 & -\lambda & 0 \\ -\frac{c_5\Omega}{\gamma}\epsilon & -\frac{c_5\Omega}{\gamma} & 0 & 0 & 0 & -\lambda \end{bmatrix}$$

The characteristic equation $\Delta(\lambda) = 0$ is

$$\lambda^6 + \frac{c_5\Omega}{\gamma}\lambda^4 - c_4\Omega\lambda^2 - (1-\epsilon)c_4c_5\frac{\Omega^2}{\gamma} = 0 \quad (D7)$$

Equation (D7) is a cubic equation in λ^2 . Let the roots be

$$\lambda_1, -\lambda_1, \lambda_2, -\lambda_2, \lambda_3, -\lambda_3$$

Then by the confluent form of Sylvester's theorem,

$$e^A = \sum_{i=1}^r \frac{1}{(\alpha_i - 1)!} \frac{d^{\alpha_i - 1}}{d\lambda^{\alpha_i - 1}} \left[\frac{e^{\lambda F(\lambda)}}{\prod_{k \neq i} (\lambda - \lambda_k)^{\alpha_k}} \right]_{\lambda = \lambda_i} \quad (D8)$$

where $F(\lambda)$ is the adjoint matrix, r is the number of distinct roots, and α_i is the multiplicity of the i^{th} root.

If the roots are all distinct, this relation becomes

$$e^A = \sum_{i=1}^3 \frac{e^{\lambda_i F(\lambda_i)} - e^{-\lambda_i F(-\lambda_i)}}{2\lambda_i \prod_{j \neq i} (\lambda_i - \lambda_j)(\lambda_i + \lambda_j)} \quad (D9)$$

where the adjoint matrix $F(\lambda)$ is given by

$$F(\lambda) = - \begin{bmatrix} \lambda^5 + \frac{c_5\Omega}{\gamma}\lambda^3 & c_4\Omega\lambda & \lambda^4 + \frac{c_5\Omega}{\gamma}\lambda^2 & \lambda^3 + \frac{c_5\Omega}{\gamma}\lambda & \lambda^2 + c_5\frac{\Omega}{\gamma} & c_4\Omega \\ -\epsilon c_5\frac{\Omega}{\gamma}\lambda^3 & \lambda^5 - c_4\Omega\lambda & -\epsilon \frac{c_5\Omega}{\gamma}\lambda^2 & -\epsilon \frac{c_5\Omega}{\gamma}\lambda & -\epsilon \frac{c_5\Omega}{\gamma} & \lambda^4 - c_4\Omega \\ c_4\Omega\lambda^2 + (1-\epsilon)c_4c_5\frac{\Omega^2}{\gamma} & c_4\Omega\lambda^2 & \lambda^5 + \frac{c_5\Omega}{\gamma}\lambda^3 & \lambda^4 + \frac{c_5\Omega}{\gamma}\lambda^2 & \lambda^3 + \frac{c_5\Omega}{\gamma}\lambda & c_4\Omega\lambda \\ c_4\Omega\lambda^3 + (1-\epsilon)c_4c_5\frac{\Omega^2}{\gamma}\lambda & c_4\Omega\lambda^3 & c_4\Omega\lambda^2 + (1-\epsilon)\frac{c_4c_5\Omega^2}{\gamma} & \lambda^5 + \frac{c_5\Omega}{\gamma}\lambda^3 & \lambda^4 + \frac{c_5\Omega}{\gamma}\lambda^2 & c_4\Omega\lambda^2 \\ c_4\Omega\lambda^4 + (1-\epsilon)c_4c_5\frac{\Omega^2}{\gamma}\lambda^2 & c_4\Omega\lambda^4 & c_4\Omega\lambda^3 + (1-\epsilon)\frac{c_4c_5\Omega^2}{\gamma}\lambda & c_4\Omega\lambda^2 + (1-\epsilon)\frac{c_4c_5}{\gamma}\Omega^2 & \lambda^5 + \frac{c_5\Omega}{\gamma}\lambda^3 & c_4\Omega\lambda^3 \\ -\frac{\epsilon c_5\Omega}{\gamma}\lambda^4 & \frac{c_5\Omega}{\gamma}\lambda^4 + (1-\epsilon)\frac{c_4c_5\Omega^2}{\gamma} & -\epsilon \frac{c_5\Omega}{\gamma}\lambda^3 & -\epsilon \frac{c_5\Omega}{\gamma}\lambda^2 & -\epsilon \frac{c_5\Omega}{\gamma}\lambda & \lambda^5 - c_4\Omega\lambda \end{bmatrix} \quad (D10)$$

From equations (D9) and (D10), the elements Ω_{ij} are seen to be given by

$$\left. \begin{aligned} \Omega_{44} &= - \sum_{i=1}^3 \frac{\lambda_i^4 + \frac{c_5 \Omega}{\gamma} \lambda_i^2}{\prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \cosh \lambda_i \\ \Omega_{45} &= - \sum_{i=1}^3 \frac{\lambda_i^4 + \frac{c_5 \Omega}{\gamma} \lambda_i^2}{\lambda_i \prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \sinh \lambda_i \\ \Omega_{46} &= - \sum_{i=1}^3 \frac{c_4 \Omega \lambda_i^2}{\lambda_i \prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \sinh \lambda_i \\ \Omega_{54} &= - \sum_{i=1}^3 \frac{c_4 \Omega \lambda_i^2 + \frac{c_4 c_5 \Omega^2}{\gamma} (1 - \epsilon)}{\lambda_i \prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \sinh \lambda_i \\ \Omega_{55} &= \Omega_{44} \\ \Omega_{56} &= - \sum_{i=1}^3 \frac{c_4 \Omega \lambda_i^2}{\prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \cosh \lambda_i \\ \Omega_{64} &= - \sum_{i=1}^3 \frac{-\epsilon c_5 \frac{\Omega}{\gamma} \lambda_i}{\prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \sinh \lambda_i \\ \Omega_{65} &= - \sum_{i=1}^3 \frac{-\epsilon c_5 \frac{\Omega}{\gamma} \lambda_i}{\lambda_i \prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \cosh \lambda_i \\ \Omega_{66} &= - \sum_{i=1}^3 \frac{\lambda_i^4 - c_4 \Omega}{\prod_{j \neq i} (\lambda_i^2 - \lambda_j^2)} \cosh \lambda_i \end{aligned} \right\} \quad (D11)$$

The value of the determinant in equation (D6) must be plotted against the frequency; the value of the frequency for which this determinant becomes zero is thereby obtained. This procedure involves first solving the cubic equation (D7)

for each assumed value of frequency parameter and then calculating the elements of the determinant from equations (D11). The process is evidently long and laborious.

ANALYSIS OF THRUST AUGMENTATION OF TURBOJET ENGINES BY WATER INJECTION AT COMPRESSOR INLET INCLUDING CHARTS FOR CALCULATING COMPRESSION PROCESSES WITH WATER INJECTION¹

By E. CLINTON WILCOX and ARTHUR M. TROUT

SUMMARY

A psychrometric chart having total pressure (sum of partial pressures of air and water vapor) as a variable, a Mollier diagram for air saturated with water vapor, and charts showing the thermodynamic properties of various air-water vapor and exhaust gas-water vapor mixtures are presented as aids in calculating the thrust augmentation of a turbojet engine resulting from the injection of water at the compressor inlet.

Curves are presented that show the theoretical performance of the augmentation method for various amounts of water injected and the effects of varying flight Mach number, altitude, ambient-air temperature, ambient relative humidity, compressor pressure ratio, and inlet-diffuser efficiency. Numerical examples, illustrating the use of the psychrometric chart and the Mollier diagram in calculating both compressor-inlet and compressor-outlet conditions when water is injected at the compressor inlet, are presented.

For a typical turbojet engine operating at sea-level zero flight Mach number conditions, the maximum theoretical ratio of augmented to normal thrust, when a nominal decrease in compressor efficiency with water injection was assumed, was 1.29. The ratio of augmented liquid consumption to normal fuel flow for these conditions, assuming complete evaporation, was 5.01. Both the augmented thrust ratio and the augmented liquid ratio increased rapidly as the flight Mach number was increased and decreased as the altitude was increased. Although the thrust augmentation possible from saturating the compressor-inlet air is very low at low flight speeds, appreciable gains in thrust are possible at high flight Mach numbers. For standard sea-level atmospheric temperature, the relative humidity of the atmosphere had a small effect on the augmented thrust ratio for all flight speeds investigated. For sea-level zero flight Mach number conditions, the augmented thrust ratio increased as the atmospheric temperature increased for low values of atmospheric relative humidity. Water injection therefore tends to overcome the loss in take-off thrust normally occurring at high ambient temperatures. For very high atmospheric relative humidities, the ambient temperature had only a small effect on the augmented thrust ratio.

INTRODUCTION

One method of augmenting the thrust of turbojet engines is to inject water or a nonfreezing mixture of water and alcohol into the air entering the compressor of the engine. The evaporation of this injected liquid extracts heat from the air and results, for the same compressor work input, in a higher compressor pressure ratio. This increased pressure

ratio is reflected throughout the engine and increases both the mass flow of gases through the engine and the exhaust-jet velocity; both factors increase the thrust produced by the engine.

An analysis of the evaporative cooling process can be conveniently divided into two phases: (1) The cooling occurring at constant pressure before the air enters the compressor, and (2) the additional cooling associated with further evaporation during the mechanical compression process. Analysis of both phases of the evaporative cooling process and the thrust augmentation produced for a typical turbojet engine were conducted at the NACA Lewis laboratory during 1947-48 and are described herein.

A specialized psychrometric chart that permits calculation of the constant-pressure evaporation process was developed and is presented. This psychrometric chart differs from the usual form, which is valid for only one value of total pressure (sum of partial pressures of air and water vapor), in that pressure is included as a variable and the temperature range has been greatly extended.

The evaporation of water during the mechanical compression process greatly complicates the calculation of this portion of the turbojet-engine cycle by conventional methods because of the trial-and-error solution involved. In order to provide a more convenient method for calculating a compression process during which evaporative cooling occurs, a Mollier diagram for air saturated with water vapor was developed. This Mollier diagram is similar to that presented in reference 1, but the ranges of temperature and pressure are extended to values suitable for use in turbojet-engine-compressor problems.

As a further aid in calculating the turbojet-engine cycle when water is injected at the compressor inlet, curves are presented giving the thermodynamic properties of the working fluid for both the compression and expansion processes. The use of both the psychrometric chart and the Mollier diagram is illustrated by means of numerical examples.

The performance of a turbojet engine utilizing thrust augmentation by water injection at the compressor inlet was evaluated over a range of flight Mach numbers and altitudes and for a range of water-injection rates. The effect on thrust augmentation of varying ambient-air temperature, relative humidity, compressor pressure ratio, and inlet-diffuser efficiency was also investigated. A comparison of the water-injection method of thrust augmentation with other thrust-augmentation methods is presented in references 2 and 3.

¹ Supersedes NACA TN 2104, "Theoretical Turbojet Thrust Augmentation by Evaporation of Water during Compression as Determined by Use of a Mollier Diagram" by Arthur M. Trout, 1950, and NACA TN 2105, "Turbojet Thrust Augmentation by Evaporation of Water Prior to Mechanical Compression as Determined by Use of Psychrometric Chart" by E. Clinton Wilcox, 1950.

ASSUMPTIONS AND METHODS OF ANALYSIS

In evaluating the performance of a turbojet engine utilizing water injection at the compressor inlet, the psychrometric chart was used to obtain the compressor-inlet conditions, the Mollier diagram was used to obtain the conditions at the end of the evaporation process in the compressor, and the remainder of the turbojet-engine cycle was calculated by conventional step-by-step methods.

The following discussion is a description of (a) the assumptions and the methods used in deriving the psychrometric chart and the Mollier diagram, and (b) the assumed design constants and component efficiencies of the turbojet engine used to illustrate performance with water injection at the compressor inlet. All symbols used in the analysis are defined in appendix A and the derivations of the equations necessary for obtaining the psychrometric chart and the Mollier diagram are presented in appendix B.

PSYCHROMETRIC CHART

The familiar psychrometric chart used in air-conditioning calculations is generally limited to values of total pressure (sum of partial pressures of air and water vapor) very near standard sea-level total pressure and to relatively low temperatures, usually less than 300° F. Inasmuch as the conditions of temperature and pressure at the compressor inlet of a turbojet engine vary widely over ranges not included in the usual psychrometric chart, the chart described herein was constructed to include these ranges.

In deriving the psychrometric chart, the following assumptions were made:

(a) The air and the water vapor are always at the same temperature.

(b) Dalton's law of partial pressures is valid for the mixture.

(c) The thermodynamic properties of water vapor are functions only of temperature for the range of vapor pressures considered.

(d) Air is a perfect gas.

By means of these assumptions, the theory of mixtures, the thermodynamic data for air and water vapor contained in references 4 and 5, respectively, and the equations derived in appendix B, a psychrometric chart with pressure as a variable and for temperatures up to 1500° R was constructed.

MOLLIER DIAGRAM

Because of the somewhat involved and tedious trial-and-error methods generally used for calculating compression processes during which water is evaporated, the Mollier diagram described in this report was prepared to provide a more direct solution of this particular problem.

The data presented in the Mollier diagram were calculated using the following assumptions:

(a) All values presented on the diagram are for a saturated mixture containing 1 pound of air.

(b) The water vapor and the air in the mixture are at the same temperature.

(c) Dalton's law of partial pressures is valid for the mixture.

(d) Air is a perfect gas.

The data presented in the Mollier diagram were calculated using the aforementioned assumptions, the thermodynamic properties data for air and water vapor presented in references 4 and 5, respectively, and the equations derived in appendix B.

Examples of the use of the psychrometric chart and the Mollier diagram are given in the subsequent section DISCUSSION OF CHARTS and in appendix C.

THRUST-AUGMENTATION CALCULATIONS

From an examination of experimental data of complete turbojet engines and of the compressor component alone, both operating with water injection at the compressor inlet, it is apparent that two prime factors cause deviation of the experimentally obtained results from the ideal process. These two factors are the decrease in compressor adiabatic efficiency that occurs with water injection and the failure of all the injected water to evaporate within the confines of the compressor. The decrease in compressor efficiency apparently is a function of the water-injection rate; however, the magnitude of the effect varies considerably with the particular compressor design. Because of the fundamental nature of the effect of compressor efficiency on the turbojet-engine cycle, its effect is relatively obscure and, for the present analysis, an arbitrary variation with water-injection rate was assumed that is representative of the effect experimentally observed in a current compressor. The theoretical results obtained are thus not expected to agree completely with experimental data obtained for engines embodying different compressor designs. The influence of this assumed decrease in compressor efficiency on the performance of the water-injection method of thrust augmentation will be indicated herein.

The degree of evaporation of water varies widely with the mode of injection and the engine operating conditions; however, insufficient data are available to determine the quantitative effects of these conditions on the degree of evaporation. Inasmuch as the thrust produced by the engine is primarily affected by the amount of water that is evaporated, the influence of incomplete evaporation can be evaluated simply by increasing the injected-water rate commensurate with the desired degree of evaporation. In the present analysis, all performance calculations have therefore been made by assuming complete evaporation.

The augmented thrust ratios experimentally obtained for engines embodying centrifugal-flow-type compressors agree quite well with those theoretically predicted herein for the condition of a saturated mixture throughout the compression process. For engines having axial-flow-type compressors, however, the efficacy of the water-injection method is considerably reduced because of centrifugal separation of the water from the air in passing through the compressor. In order to avoid the centrifugal-separation effect, the water must be injected at several stages throughout the compressor.

Inasmuch as considerable increase in thrust is attainable at high inlet temperatures or high flight Mach numbers merely by saturating the compressor-inlet air with water, the performance of the water-injection method has been determined for both the condition of saturation throughout the compression process and saturation only of the compressor-inlet air. The thrust increases obtained for the condition of saturation throughout the compression process are believed indicative of the increases possible for engines having centrifugal-flow compressors, whereas the thrust increases shown for the condition of saturated inlet air are more nearly equal to the possibilities of the water-injection method when applied to an engine having an axial-flow compressor and not utilizing interstage injection. Experimental investigations of interstage injection indicate that the thrust increases available for this method lie between those attainable for saturated inlet air and those obtained by saturation throughout the compression process. The decreased thrust augmentation obtainable with an engine having an axial-flow compressor utilizing interstage injection may be due to the increased sensitivity of the efficiency of this type compressor to water injection.

In order to determine the theoretical thrust augmentation made possible by evaporation of water during compression, step-by-step calculations of normal and augmented thrust for a typical turbojet engine operating under various flight conditions were made. The psychrometric chart was used to determine the compressor-inlet conditions and the Mollier diagram to calculate the conditions at the end of the evaporation process in the compressor with water injection. Equations used in the step-by-step calculations are given in appendix D. It was assumed that the inlet air was diffused to a sufficiently low velocity so that the static temperature at the compressor inlet did not appreciably differ from the total temperature.

The component efficiencies chosen for the typical turbojet engine were: inlet-diffuser adiabatic efficiency (except where otherwise noted), 0.85 up to a flight Mach number of 1.0, linearly decreasing to 0.75 at a flight Mach number of 2.0 (these values of diffuser efficiency correspond to total-pressure recovery ratios of 0.915 and 0.66 at flight Mach numbers of 1.0 and 2.0, respectively); compressor adiabatic efficiency, 0.80; turbine adiabatic efficiency, 0.85; and exhaust-nozzle adiabatic efficiency, 0.95. The compressor adiabatic efficiency is defined as the ratio of isentropic to actual work.

For the compression process with evaporative cooling, it must be recalled that a higher pressure ratio is obtained for a given isentropic work than is obtained with dry air. Inasmuch as experimental data of compressor performance with water injection indicate a decrease in compressor adiabatic efficiency, the compressor efficiency η_c was arbitrarily assumed to decrease according to the relation $\eta_c = 0.80 - \Delta X_c$, where ΔX_c is the change in water vapor-air ratio in the compressor. This decrease in compressor efficiency was assumed for all conditions of altitude and flight Mach number, except when it was desired to show the effect of this assumption on performance. A single-stage, centrifugal-flow compressor with a tip speed of 1500 feet per second

and a slip factor of 0.95 was assumed for all of the calculations except when it was desired to show the effect of normal compressor pressure ratio. For the assumed values of compressor tip speed, slip factor, and efficiency, the resulting compressor pressure ratio for sea-level zero flight Mach number conditions with no water injection was 4.61. The normal engine performance would be equally applicable to an engine having an axial-flow compressor with the same enthalpy rise, pressure ratio, and compressor efficiency. A combustion-chamber pressure loss of 3 percent and a turbine-inlet temperature of 2000° R were assumed. The ambient relative humidity was assumed to be 0.50 except when it was desired to show the effect of varying ambient relative humidity. All liquid water was assumed injected at the compressor inlet at a temperature of 519° R and the air was assumed to remain saturated as long as any liquid water was present. For conditions where all the injected water evaporated before the end of the compression process, that portion of the process occurring after evaporation was calculated from the thermodynamic relations for an adiabatic compression by using the appropriate thermodynamic properties of the resulting air-water vapor mixtures. The adiabatic efficiency of this portion of the compression process was assumed equal to that previously described for the compression process during which evaporation occurred. Calculations were made for flight Mach numbers up to 2.0 and for standard altitudes of sea level and 35,332 feet.

In order to simplify the calculations of the adiabatic compression occurring after the evaporation of all the injected water and the expansion processes occurring in the turbine and the exhaust nozzle, curves of the thermodynamic properties of air-water vapor and exhaust gas-water vapor mixtures were obtained. These curves were obtained from the theory of mixtures and the thermodynamic data for air, water vapor, and exhaust gases.

Because of the low temperatures occurring at high altitudes, a nonfreezing mixture of water and alcohol rather than water alone is usually employed for compressor-inlet injection. Although all the results presented herein are based on the injection of only water at the compressor inlet, they are probably equally applicable to the injection of water-alcohol mixtures because of the close agreement experimentally obtained between results for water- and for water-alcohol-mixture injection.

DISCUSSION OF CHARTS

PSYCHROMETRIC CHART

In the psychrometric chart (fig. 1), total enthalpy is plotted against dry-bulb temperature for various values of water-air ratio. Also included are curves of the ratio of relative humidity to relative pressure, where relative pressure is the ratio of static pressure to standard sea-level static pressure. Inasmuch as evaporation occurs at constant pressure, the value of relative pressure is unchanged by water injection. The curves of constant water-air ratio are approximately straight lines having a positive slope and the curves of constant ratio of relative humidity to relative

FIGURE 1.—Psychrometric chart. (A 23- by 25-inch print of this figure is available from NACA upon request.)

pressure are curved upward. The enthalpy scale was arbitrarily chosen so that the enthalpy of a saturated mixture of air and water vapor at a temperature of 519° R and a pressure of 14.696 pounds per square inch was 100 Btu per pound of air.

The temperature resulting after water evaporation may be obtained from figure 1 for a wide range of initial air temperatures and pressures. The temperature can be determined either for the evaporation of a given amount of water or for any final relative humidity.

In the construction of figure 1, the enthalpy of liquid water was assumed to be zero at 519° R. The chart values are thus directly applicable to cases where the water is injected at this temperature. For temperatures of liquid water only slightly different from 519° R, the errors involved in the chart are negligible; however, for extremely accurate work or for temperatures of injected water greatly different from 519° R, corrections must be made for the enthalpy of liquid water. These corrections are the same as the enthalpy corrections for the Mollier diagram discussed in appendix C, and consist in adding the enthalpy of liquid water at the start of the process and, if any liquid remains at the end of the process, subtracting the enthalpy of the remaining liquid.

The method of using the chart is indicated by the following illustrative cases:

Example 1.—For initially dry air at a temperature of 1260° R, assume that sufficient water is injected to give a final water-air ratio of 0.05. From figure 1, the total enthalpy is 271.6 Btu per pound of air for a temperature of 1260° R and a water-air ratio of 0. (For this example and all following examples, the values have been read from the large prints of figs. 1 or 2, which are available from the NACA on request and are more convenient to use when a high degree of accuracy is desirable.) Inasmuch as the evaporation occurs at constant total enthalpy, the temperature after evaporation can be determined from the initial total enthalpy and the final water-air ratio. For a total enthalpy of 271.6 Btu per pound of air and a water-air ratio of 0.05, the temperature is 1008° R. The temperature drop is then 252 F° for these particular conditions.

Example 2.—In order to illustrate the use of the chart in obtaining the temperature and the water-air ratio necessary to saturate air from a given set of initial conditions, initially dry air at a temperature of 1060° R and at twice standard sea-level static pressure is assumed. The enthalpy corresponding to a temperature of 1060° R and a water-air ratio of 0 is 221.0 Btu per pound of air. The value of relative humidity for saturation is 1.0 and for these conditions the value of relative pressure δ is 2.0. The temperature and the water-air ratio are 613° R and 0.0995, respectively, at an enthalpy of 221.0 Btu per pound of air and a ratio of relative humidity to relative pressure ϕ/δ of 0.5. For these conditions, the initial mixture may be cooled 447 F° by injecting 0.0995 pound of water per pound of air.

Example 3.—The use of the chart in obtaining temperatures resulting from water evaporation when some water is initially present in the air is the same as that previously described, except that the starting enthalpy is found from the initial water-air ratio and temperature. For example, for the conditions of temperature and pressure in example 2 and an initial water-air ratio of 0.02, the initial enthalpy is 247.0 Btu per pound of air. The saturation temperature for an enthalpy of 247.0 Btu per pound and a value of ϕ/δ of 0.5 is 620° R and the final water-air ratio is 0.122. For these conditions, cooling the initial mixture 440 F° is therefore possible by evaporating 0.102 pound of water per pound of air.

The effect of initial temperature and pressure on the amount of cooling possible from saturation can be readily seen from figure 1. For a constant pressure and consequent constant value of ϕ/δ ($\phi=1$), the amount of cooling possible increases as the initial temperature is raised. For a constant temperature, increasing the pressure decreases the value of ϕ/δ and, from figure 1, decreasing the value of ϕ/δ decreases the amount of cooling obtained. In general, when some water vapor is initially present, the cooling possible from saturation and the amount of water that must be injected to obtain saturation are somewhat less than those for dry air. In some instances, however, depending on the particular initial conditions, the amount of water that must be injected to obtain saturation is greater when some water vapor is initially present than for dry air, as illustrated in examples 2 and 3.

Example 4.—In order to illustrate the method of using the psychrometric chart when water is injected at a temperature other than 519° R and the enthalpy of the injected water is to be considered, assume that it is desired to saturate initially dry air at a temperature of 910° R and standard sea-level pressure with water injected at a temperature of 619° R. From figure 1, which is correct for water injected at 519° R, the initial enthalpy of the air at a temperature of 910° R is 183.5 Btu per pound. For a value of relative humidity divided by relative pressure of 1.0 (saturation at standard sea-level pressure) and an enthalpy of 183.5 Btu per pound, the temperature is 577° R and the water-air ratio is 0.075. If the water were injected at 519° R, cooling the air 333 F° would be possible by injecting sufficient water to obtain a water-air ratio of 0.075. For water not injected at 519° R, an estimate must be made of the final water-air ratio in order to determine the starting condition. For the present example, assume that the final water-air ratio is 0.08. From the insert of figure 2, the enthalpy of liquid water at a temperature of 619° R is 100 Btu per pound of water. The new starting enthalpy is now 183.5 plus 8.0 (water-air ratio, 0.08) or 191.5 Btu per pound. For a value of ϕ/δ of 1.0 and an enthalpy of 191.5 Btu per pound, the temperature is 579° R and the water-air ratio is 0.081. If water were injected at a temperature of 619° R, the cooling obtained from saturation would therefore be 331 F° and the required water-air ratio would be 0.081.

FIGURE 2.—Mollier diagram. (Ten 16-by 21-inch expanded sectional prints available from NACA upon request.)

MOLLIER DIAGRAM

The Mollier diagram (fig. 2) is so constructed that each point represents values for 1 pound of air plus the water vapor necessary for saturation. The abscissa is entropy (in Btu/(lb air)(°R)) and the ordinate is enthalpy (in Btu/lb air). The solid slanting lines with positive slope are lines of constant pressure in pounds per square inch. The broken lines with positive slope are lines of constant temperature (in °R). The solid lines of negative slope are lines of constant weight ratio of water vapor to air. Data are presented for pressures from 3 to 500 pounds per square inch and temperatures from 440° to 790° R. The entropy and the enthalpy of liquid water were assumed to be zero at 519° R and the bases for enthalpy and entropy of air were so fixed that at a temperature of 519° R and a pressure of 14.696 pounds per square inch the enthalpy of the saturated mixture is 100 Btu per pound of air and the entropy is 0.10 Btu/(lb air)(°R). When liquid water is present at a temperature other than 519° R, corrections for enthalpy and entropy must be made. These corrections are discussed in appendix B and a chart giving enthalpy and entropy of liquid water at various temperatures to be used for these corrections is shown on the Mollier diagram.

In order to utilize the Mollier diagram to calculate compressor-outlet conditions with evaporation of water during compression, knowledge of the conditions of the saturated air at the compressor inlet and the actual and isentropic work of the compression process is necessary. The conditions at the end of the saturated compression process may be obtained as follows:

A point is found on the Mollier diagram corresponding to the conditions of saturated air at the compressor inlet. An isentropic compression process is then followed on the diagram and a second point determined by moving vertically along a line of constant entropy until a value of enthalpy equal to the original enthalpy plus the enthalpy of the isentropic work of compression per pound of air (actual work/lb of air multiplied by adiabatic efficiency) is reached. The pressure read from the diagram at this second point is the pressure at the end of the compression process. The final temperature and water-air ratio for the compression process are read from the diagram at a third point, which is obtained by following a constant-pressure line from the second point until a value of enthalpy equal to the original enthalpy plus the enthalpy of the actual work of compression per pound of air is reached.

For a centrifugal-flow compressor, all the water to be evaporated during compression is added at the compressor inlet and the compressor enthalpy rise may be calculated per unit mass flow of the mixture of air and water vapor at the compressor outlet from considerations of tip speed and slip factor. Inasmuch as all values on the Mollier diagram are per unit mass flow of air, the value of enthalpy rise per unit mass flow of mixture at the compressor outlet must be converted to enthalpy rise per unit mass flow of air in order to use the chart. For an axial-flow compressor, if all the water is injected at the compressor inlet, centrifugal separation of the air and water greatly reduces the effects of water

injection and therefore injection of the water in several stages along the compressor length is desirable. If calculations for interstage water injection of this type are desired, the total enthalpy rise must be divided among the sections of the compressor between injection points and calculations similar to those for the centrifugal-flow compressor must be made for each section in order to allow for the change in mass flow from section to section and the corresponding change in enthalpy rise per unit mass flow of air.

When less water is injected than is necessary to saturate the air at the compressor outlet, the compression process is divided into two parts: (1) an adiabatic compression of a saturated mixture, which may be calculated by use of the Mollier diagram, and (2) further adiabatic compression of the resulting mixture of air and water vapor.

The following numerical example is presented to illustrate the method of using the Mollier diagram to calculate the compressor-outlet conditions for a saturated compression process:

Assume that a compressor having an adiabatic efficiency of 0.80 and imparting an enthalpy rise of 80 Btu per pound of air to the working fluid is operated with sufficient water injected at the compressor inlet at a temperature of 519° R to maintain saturation at all times. Further, assume that the inlet air has a relative humidity of 0.50 at a temperature of 530° R and a pressure of 14.7 pounds per square inch and that it is desired to find the compressor-outlet pressure P_3 , -outlet temperature T_3 , -outlet water vapor-air ratio X_3 , and the amount of water evaporated during the process.

The conditions at the compressor inlet after saturation can be obtained from the psychrometric chart (fig. 1). For the initial condition of ambient relative humidity ϕ of 0.50, temperature T_0 of 530° R, and pressure P_0 of 14.7 pounds per square inch, the water vapor-air ratio X_0 is 0.0077 and the enthalpy H_0 is 100 Btu per pound of air.

After saturation at constant pressure, from figure 1, the temperature T_1 is 519° R, the water vapor-air ratio X_1 is 0.0106, and the enthalpy H_1 is 100 Btu per pound of air.

From the Mollier diagram (fig. 2), for a temperature T_1 of 519° R and a pressure P_1 of 14.7 pounds per square inch, the entropy S_1 is 0.10 Btu/(lb air)(°R).

By increasing the enthalpy at constant entropy by an amount equal to the ideal work of compression, the actual pressure at the compressor outlet may be read from the diagram. The ideal work of compression is

$$\Delta H_{c,i} = \eta_c \Delta H_c = 0.80 \times 80 = 64 \text{ (Btu/lb air)}$$

and

$$H_{2,i} = H_1 + \Delta H_{c,i} = 100 + 64 = 164 \text{ (Btu/lb air)}$$

The value of pressure read from the diagram at an enthalpy of 164 Btu per pound of air and an entropy of 0.10 Btu/(lb air)(°R) is

$$P_3 = 70.7 \text{ (lb/sq in.)}$$

The enthalpy at the compressor outlet is equal to the enthalpy at the inlet plus the actual enthalpy change, or

$$H_3 = H_1 + \Delta H_c = 100 + 80 = 180 \text{ (Btu/lb air)}$$

From the Mollier diagram at a pressure of 70.7 pounds per square inch and an enthalpy of 180 Btu per pound of air, the values of temperature and water vapor-air ratio at the compressor outlet are

$$T_3 = 630^\circ \text{R and } X_3 = 0.0583$$

The amount of water evaporated is

$$X_3 - X_0 = (X_1 - X_0) + (X_3 - X_1) = (0.0106 - 0.0077) + (0.0583 - 0.0106) = 0.0506 \text{ (lb water/lb air)}$$

The amount of water vapor represented by $X_1 - X_0$ is that evaporated at the inlet prior to compression and the amount $X_3 - X_1$ represents that water evaporated during the mechanical compression process.

Additional examples presented in appendix C illustrate the use of the Mollier diagram in calculating a compression process when the water is injected at a temperature other than 519°R and when a given amount of water (less than the amount required to saturate the compressor-outlet air) is injected.

(a) Air-water vapor mixture. Temperature, 600°R .

FIGURE 3.—Thermodynamic properties of mixtures at pressure of 0 pound per square inch absolute.

MIXTURE PROPERTIES FOR COMPRESSOR

A chart of the thermodynamic properties of water vapor-air mixtures is shown in figure 3(a). The variation of specific heat at constant pressure with temperature and pressure is small in the range of interest for compressor calculations; figure 3(a) was therefore based on an average temperature of 600°R and zero pressure. Values of the ratio of specific heats γ_m , gas constant R_m , and specific heat at

constant pressure $c_{p,m}$ are plotted for various values of the water vapor-air ratio X . The data presented in this chart were used in calculating compressor-outlet conditions for those cases where less water was injected than the amount necessary to saturate the air at the compressor outlet. The use of figure 3(a) for a case of this type is illustrated in Sample Calculation II (appendix C). The thermodynamic data for air and water vapor used in obtaining the data of figure 3(a) were obtained from references 4 and 5, respectively, and the values presented are for 1 pound of mixture of air and water vapor.

(b) Exhaust gas-water vapor mixture. Temperature, 1650°R ; hydrogen-carbon ratio, 0.175.
FIGURE 3.—Concluded. Thermodynamic properties of mixtures at pressure of 0 pound per square inch absolute.

MIXTURE PROPERTIES FOR TURBINE AND JET

A chart of the thermodynamic properties of water vapor-exhaust gas mixtures for a temperature of 1650°R is shown in figure 3(b). Values for the ratio of specific heats γ_e , gas constant R_e , and specific heat at constant pressure $c_{p,e}$ are plotted for various values of the water vapor-air ratio X and the fuel-air ratio f/a . The thermodynamic data for water vapor and exhaust gases necessary for obtaining the data presented in figure 3(b) were obtained from references 5 and 6, respectively, and the values presented are for 1 pound of mixture of exhaust gas and water vapor. (A hydrogen-carbon ratio of the fuel of 0.175 was assumed in preparing these curves.) Although the actual values of γ_e and $c_{p,e}$ vary with temperature, the values given in figure 3(b) can be used for an appreciable temperature range with negligible error because of the compensating manner in which γ_e and $c_{p,e}$ enter the equations for an expansion process. For more accurate work, the method

presented in reference 7 may be used for calculating the expansion process.

FIGURE 4.—Effect of flight conditions and ratio of augmented to normal liquid flow on thrust augmentation.

DISCUSSION OF AUGMENTATION RESULTS

EFFECT OF WATER-INJECTION RATE

In figure 4, the augmented thrust ratio (ratio of augmented thrust to normal thrust) is shown as a function of the augmented liquid ratio (ratio of augmented total liquid flow to normal fuel flow) for three different operating conditions: flight Mach numbers of 0 and 1.5 at sea-level altitude and a flight Mach number of 1.5 at an altitude of 35,332 feet. The points on the curves indicated by circles represent the case where only sufficient water to saturate the compressor-inlet air is injected with no evaporation occurring during mechanical compression. The end points on the curves represent the condition where the air at the compressor outlet is saturated and indicate the maximum amounts of augmentation theoretically possible by evaporation of water before and during compression in the engine previously described and for the given flight conditions. As the augmented liquid ratio is increased by increasing the amount of injected water, the augmented thrust ratio increases but at a slightly decreasing rate. At sea-level, zero flight Mach number conditions for saturation only up to the compressor inlet, the augmented thrust ratio is 1.035 and the augmented liquid ratio is 1.18. As the augmented liquid ratio is increased by evaporating more water during mechanical compression, the augmented thrust ratio increases to 1.29 at an augmented liquid ratio of 5.01 for compressor-outlet saturation. For a given altitude, increasing the flight Mach number increases the compressor-inlet temperature, which permits the evaporation of more water and thereby increases the maximum

augmented thrust and augmented liquid ratios as well as increasing the augmented thrust ratio for a given augmented liquid ratio. At a sea-level flight Mach number of 1.5 for saturation of the compressor-outlet air, the augmented thrust ratio is 2.07 and the augmented liquid ratio is 10.66. Increasing the altitude for a given flight Mach number results in a decreased compressor-inlet temperature, thereby reducing the amount of water that may be evaporated. At an altitude of 35,332 feet and a flight Mach number of 1.5 for compressor-outlet saturation, the augmented thrust ratio is 1.53 at an augmented liquid ratio of 6.85.

EFFECT OF OPERATING CONDITIONS FOR SATURATED COMPRESSOR-INLET AND COMPRESSOR-OUTLET CONDITIONS

Effect of flight Mach number, altitude, and inlet-diffuser efficiency.—The augmented thrust and augmented liquid ratios are shown as functions of flight Mach number for altitudes of sea level and 35,332 feet and for various values of inlet-diffuser efficiency in figure 5 for compressor-inlet

(a) Augmented thrust ratios.

(b) Augmented liquid ratios.

FIGURE 5.—Effect of flight Mach number and altitude on augmented thrust and augmented liquid ratios for various values of inlet-diffuser efficiency. Sufficient water injected to saturate compressor-inlet air.

FIGURE 6.—Effect of flight Mach number and altitude on augmented thrust and augmented liquid ratios for various values of inlet-diffuser efficiency. Sufficient water injected to saturate compressor-outlet air.

saturation, and in figure 6 for compressor-outlet saturation. In order to indicate the magnitude of the thrust available, relative-thrust curves (constant values of the ratio of thrust to thrust available at sea-level, zero flight Mach number conditions for operation without water injection) are superimposed on the curves of figures 5(a) and 6(a). Both the augmented thrust ratio and the augmented liquid ratio increase rapidly as the flight Mach number is increased and decrease as the altitude is increased. Although the augmented thrust ratio available at a given flight Mach number increases at decreased values of inlet-diffuser efficiency, the

actual thrust available decreases because of the deterioration of the engine performance without water injection at the decreased values of inlet-diffuser efficiency.

For saturated compressor-inlet conditions (fig. 5(a)) and an inlet-diffuser adiabatic efficiency of 0.80, the augmented thrust ratio for sea-level zero flight Mach number is 1.035 and increases with increasing flight Mach number, reaching a value of 1.28 at a flight Mach number of 1.0 and 2.16 at a flight Mach number of 2.0. The corresponding augmented liquid ratios (fig. 5(b)) are 1.18, 2.40, and 9.20 for sea-level flight Mach numbers of 0, 1.0, and 2.0, respectively. For a flight Mach number of 2.0, increasing the altitude from sea level to 35,332 feet reduces the augmented thrust ratio from 2.16 to 1.48. The corresponding reduction in augmented liquid ratio is from 9.20 to 4.20. Although the thrust increases available from compressor-inlet saturation are very low at low flight Mach numbers, appreciable gains in thrust are possible at high flight speeds. Thrust augmentation by compressor-inlet-air saturation can therefore be used to good advantage not only for centrifugal-flow engines but also for axial-flow engines that require special injection systems to avoid centrifugal separation at higher injection rates.

For saturated compressor-outlet conditions and an inlet-diffuser adiabatic efficiency of 0.80, the augmented thrust ratio (fig. 6(a)) is 1.29, 1.67, and 2.88 for sea-level flight Mach numbers of 0, 1.0, and 2.0, respectively. The corresponding augmented liquid ratios (fig. 6(b)) are 5.01, 7.22, and 17.10, respectively. At a flight Mach number of 2.0, increasing the altitude from sea level to 35,332 feet reduces the augmented thrust ratio from 2.88 to 1.95 with a corresponding reduction in augmented liquid ratio from 17.10 to 10.30.

FIGURE 7.—Effect of atmospheric relative humidity on augmented thrust ratio for various flight Mach numbers. Altitude, sea level; inlet-diffuser efficiency, 0.80.

Effect of ambient relative humidity.—The augmented thrust ratio is shown in figure 7 as a function of flight Mach number for atmospheric relative humidities of 0 and 100 percent. The data shown are for standard sea-level condi-

FIGURE 8.—Effect of ambient temperature on augmented thrust and augmented liquid ratios for various ambient relative humidities. Sea-level pressure; zero flight Mach number.

tions of temperature and pressure and an inlet-diffuser efficiency of 0.80. Results are presented for the case in which sufficient water is injected to saturate the compressor-inlet air and for the case in which the amount of water required to saturate the compressor-outlet air is injected. The ambient humidity has a relatively small effect on the augmented thrust ratio, especially at high flight Mach numbers.

Effect of ambient-air temperature for various relative humidities.—The effect of ambient temperature on augmented thrust and augmented liquid ratios for various ambient relative humidities is shown in figures 8(a) and 8(b), respectively. The data shown are for zero flight Mach number and standard sea-level atmospheric pressure. Results are shown for saturated compressor-inlet and -outlet conditions and relative-thrust curves showing constant values of the ratio of augmented thrust available to the thrust available from the engine operating without water injection at an atmospheric temperature of 519° R are included.

For an atmospheric relative humidity of 100 percent, no thrust augmentation may be obtained from compressor-inlet saturation inasmuch as no evaporative cooling is possible. As atmospheric relative humidity is decreased, the augmentation increases to about 8 percent for dry air at standard

FIGURE 8.—Concluded. Effect of ambient temperature on augmented thrust and augmented liquid ratios for various ambient relative humidities. Sea-level pressure; zero flight Mach number.

sea-level temperature of 519° R. For low relative humidities, more evaporative cooling becomes possible as the ambient-air temperature is increased and at a temperature comparable to extreme summer heat (for example, 580° R) an augmented thrust ratio of 1.23 is available for dry air.

For saturated compressor-outlet air, the augmented thrust ratio for an atmospheric relative humidity of 1.00 is relatively unaffected by changes in atmospheric temperature. For an atmospheric relative humidity of 0.50, the augmented thrust ratio increases slightly and, for zero atmospheric relative humidity, a marked increase in the augmented thrust ratio occurs as the atmospheric temperature is increased. For an atmospheric temperature of 519° R, the augmented thrust ratio decreases from 1.33 to 1.24 as the atmospheric relative humidity increases from 0 to 1.00. At a temperature of 580° R, the decrease in augmented thrust ratio is from 1.55 to 1.26 for the same increase in atmospheric relative humidity.

As indicated by the relative-thrust curves in figure 8(a), the actual augmented thrust decreases as the atmospheric temperature is increased for all values of atmospheric relative humidity because of the marked decrease in normal engine thrust at increased compressor-inlet temperatures. The data of figure 8(a) indicate that thrust augmentation by water injection is one method for overcoming the marked decrease in take-off thrust accompanying high ambient-air temperatures. The augmented liquid ratios shown in figure 8(b) follow the same general trends as the augmented thrust ratios.

Effect of compressor efficiency.—As has been previously pointed out, the compressor efficiency has been decreased in

calculating the augmented engine performance with evaporation during mechanical compression in order to obtain closer agreement with experimental compressor performance with water injection. The effect of this decrease in compressor efficiency on the augmented thrust and augmented liquid ratios at various flight Mach numbers and for altitudes of sea level and 35,332 feet is shown in figure 9 for the condition of saturated compressor outlet. The results are shown for a constant value of compressor efficiency of 0.8 and for a value of compressor efficiency that has been decreased as indicated by the following relation:

$$\eta_c = 0.80 - \Delta X_c$$

FIGURE 9.—Effect of compressor-efficiency assumption on augmented thrust and augmented liquid ratios for various flight conditions. Sufficient water injected to saturate compressor-outlet air.

where ΔX_c is equal to the change in water vapor-air ratio in the compressor.

From figure 9(a), it can be seen that the assumption of a constant compressor efficiency results in values of augmented thrust ratio considerably greater than the assumption of a compressor efficiency decreasing with the change in water vapor-air ratio in the compressor. For sea-level zero flight Mach number, the augmented thrust ratio is 1.29 when a decreased value of compressor efficiency is assumed, as compared with an augmented thrust ratio of 1.50 for the assumption of a constant compressor efficiency of 0.80. For a sea-level flight Mach number of 2.0, the corresponding values of augmented thrust ratio are 3.04 and 3.44. Similar results are obtained at an altitude of 35,332 feet. Additional calculations made for a constant compressor efficiency of 0.85 gave thrust ratios approximately equal to those for a constant efficiency of 0.80, which indicates that the magnitude of compressor efficiency has little effect on thrust augmentation if the efficiency for the normal and the augmented case is assumed to be the same.

The assumption of a constant value of compressor efficiency is shown in figure 9(b) to result in values of augmented liquid ratio somewhat higher than those obtained for the assumption of a decreased value of compressor efficiency.

FIGURE 10.—Augmented thrust ratio as function of augmented liquid ratio for two normal compressor pressure ratios. Sea-level zero flight Mach number conditions.

Effect of normal compressor pressure ratio.—The augmented thrust ratio as a function of augmented liquid ratio for normal compressor pressure ratios of 4.61 and 10 is shown in figure 10. The data shown are for sea-level zero flight Mach number conditions. For any augmented liquid ratio, the engine having the high-pressure-ratio compressor gave the greatest augmented thrust ratio, with the difference

between the augmented thrust ratios for the low- and high-pressure-ratio engines increasing as the augmented liquid ratio increased. The use of a high-pressure-ratio compressor also permits operation at increased values of augmented liquid ratio and hence greater values of augmented thrust ratio. For a compressor pressure ratio of 4.61, the maximum value of augmented thrust ratio is 1.29 at an augmented liquid ratio of 5.01. For a compressor pressure ratio of 10, the maximum value of augmented thrust ratio is increased to 1.63 at an augmented liquid ratio of 10.84. The effect of compressor pressure ratio shown is based on a compressor efficiency reduced as a function of the amount of water evaporated, as previously mentioned. Because of the larger amounts of water that may be evaporated at the higher normal compressor pressure ratio, the reductions in compressor efficiency are correspondingly higher. The compressor efficiency was reduced from 0.80 for the normal condition to 0.70 for the full-augmented condition for the high-pressure-ratio compressor. Only experimental investigations of the effect of water injection on the efficiency of compressors having various pressure ratios will indicate the validity of this assumption. As previously mentioned, however, investigations of compressors having normal pressure ratios approximating that of the low-pressure-ratio compressor assumed in this investigation indicate the dependency of the compressor efficiency on the amount of water injected.

SUMMARY OF RESULTS

A psychrometric chart having total pressure as a variable and a Mollier diagram for a saturated mixture of air and water vapor were developed as aids in calculating the performance of compressors when water is injected at the compressor inlet. By use of the psychrometric chart and the Mollier diagram to calculate compressor performance, the performance of the water-injection method of thrust augmentation was evaluated over a range of flight and atmospheric conditions for a typical turbojet engine. The following results were obtained for an engine having a normal compressor pressure ratio of 4.61 at sea-level zero flight Mach number conditions when a nominal decrease in compressor efficiency with water injection was assumed:

1. For constant flight conditions, increasing the amount of water evaporated increased the ratio of augmented thrust to normal thrust and the ratio of augmented liquid flow to

normal fuel flow. For sea-level zero flight Mach number conditions and an atmospheric relative humidity of 0.50, increasing the amount of injected water from the amount required to saturate the compressor-inlet air to the amount required to saturate the compressor-outlet air increased the augmented thrust ratio from 1.035 to 1.29. The corresponding increase in augmented liquid ratio was from 1.18 to 5.01.

2. The augmented thrust and augmented liquid ratios increased rapidly as the flight Mach number was increased and decreased as the altitude increased. Although the thrust increases obtainable by compressor-inlet-air saturation were very small at low flight speeds, appreciable gains in thrust were possible at high flight Mach numbers. Thrust augmentation by compressor-inlet-air saturation can therefore be used to good advantage at high flight Mach numbers not only for centrifugal-flow engines but also for axial-flow engines that require special injection systems to avoid centrifugal separation at higher injection rates.

3. For standard atmospheric temperatures, the ambient relative humidity had only a small effect on the augmented thrust ratios produced at all flight speeds investigated.

4. For sea-level zero flight Mach number conditions and low ambient relative humidities, the augmented thrust ratio increased as the ambient-air temperature was increased. Thrust augmentation by water injection was therefore shown to be desirable for take-off use inasmuch as water injection tends to overcome the loss in take-off thrust normally occurring at high ambient temperatures. For very high atmospheric relative humidities, the effect of ambient temperature on augmented thrust ratio was small.

5. The augmented thrust ratio produced for a given set of conditions increased as the inlet-diffuser efficiency was decreased; however, because of the rapid deterioration of normal engine performance at decreased values of inlet-diffuser efficiency, the actual value of augmented thrust was decreased.

6. Increasing the normal engine compressor pressure ratio increased the maximum possible value of augmented liquid ratio and, hence, the maximum possible value of augmented thrust ratio.

APPENDIX B

DERIVATION OF EQUATIONS FOR PSYCHROMETRIC CHART AND MOLLIER DIAGRAM

PSYCHROMETRIC CHART

The equations necessary for obtaining a psychrometric chart having total pressure (sum of partial pressures of air and water vapor) as a variable may be derived in the following manner:

From the general energy equation, the enthalpy of a mixture of air, liquid water, and water vapor per pound of air is

$$H_{a,0} + X_0 H_{g,0} + (X_1 - X_0) H_{f,0} = H_{a,1} + X_1 H_{g,1} \quad (B1)$$

When only the equilibrium between air and water vapor is considered, the term involving the enthalpy of liquid water $H_{f,0}$ disappears; in order to apply equation (B1) to a particular process, however, some assumption must be made as to the temperature for which the enthalpy of liquid water is zero. For the present analysis, the enthalpy of liquid water was assumed to be zero at 519° R. The results are therefore accurate for water injected at this temperature, with only small errors resulting for water injected at a somewhat different temperature. When it is assumed that the enthalpy of liquid water is zero, equation (B1) may be stated as

$$H_{a,0} + X_0 H_{g,0} = H_{a,1} + X_1 H_{g,1} \quad (B2)$$

The total enthalpy H for condition 0 or 1 is defined as

$$H = H_a + X H_g \quad (B3)$$

The water-air ratio X is evaluated as follows:

$$X = \frac{v_a}{v_g} = \frac{p_g}{R_g t_g} \frac{R_a t_a}{p_a} \quad (B4)$$

If the temperature of the air and vaporized water are equal and Dalton's law of partial pressure is valid, equation (B4) becomes

$$X = \frac{R_a}{R_g} \frac{p_g}{p_m - p_g} \quad (B5)$$

From the definition of relative humidity ϕ , relative pressure δ , and gas constant R ,

$$\phi = \frac{p_g}{p_{g,s}} \quad (B6)$$

$$\delta = \frac{p_m}{14.696} \quad (B7)$$

and

$$R_g = \frac{p_g v_g}{t_g} \quad (B8)$$

Substituting equations (B6) to (B8) in equation (B5) gives

$$X = \frac{R_a}{\left(\frac{p_g v_g}{t_g}\right)} \frac{\phi}{\delta} \frac{p_{g,s}}{14.696} \left(1 - \frac{\phi}{\delta} \frac{p_{g,s}}{14.696}\right) \quad (B9)$$

When the water-air ratio X is replaced in equation (B3) by the value expressed in equation (B9), the expression for total enthalpy H becomes

$$H = H_a + H_g \frac{R_a}{\left(\frac{p_g v_g}{t_g}\right)} \frac{\phi}{\delta} \frac{p_{g,s}}{14.696} \left(1 - \frac{\phi}{\delta} \frac{p_{g,s}}{14.696}\right) \quad (B10)$$

The data presented in figure 1 were obtained by means of equations (B3), (B9), (B10), and the thermodynamic data for air and water vapor contained in references 4 and 5, respectively. For convenience, the enthalpy of the saturated mixture of air and water vapor at a temperature of 519° R and a pressure of 14.696 pounds per square inch was arbitrarily fixed at 100 Btu per pound of air. In using equation (B10), the enthalpies of air and water vapor obtained from references 4 and 5, respectively, must be corrected in order to satisfy the conditions of zero enthalpy of liquid water at 519° R and the condition of an enthalpy of 100 Btu per pound of air for a saturated mixture of air and water vapor at a temperature of 519° R and a pressure of 14.696 pounds per square inch. The value of enthalpy of water vapor obtained from reference 5 must be decreased by 27.06 Btu per pound in order to satisfy the first condition, and the enthalpy of air obtained from reference 4 must be increased by 60.24 Btu per pound in order to satisfy the second condition. For very accurate work, the injection of water at a temperature other than 519° R can be corrected for simply by adding the enthalpy of liquid water to find the starting point of the process and, when liquid water remains, subtracting the enthalpy of this liquid water at the end of the process. These corrections are the same as the enthalpy corrections to the Mollier diagram discussed in appendix C.

The enthalpy and the specific volume of water vapor are functions of the vapor pressure of water as well as of the temperature. In the range of temperatures and pressures encountered at the compressor inlet of a turbojet engine, however, the enthalpy of water vapor and the product of vapor pressure and specific volume can be considered as functions only of temperature for all practical purposes. For any value of temperature, the enthalpy and the specific volume were evaluated for the maximum pressure that would exist for that temperature at the compressor inlet of a turbojet engine. This maximum pressure is the pressure that would be obtained by ideal ram compression from standard sea-level temperature and pressure to the desired temperature.

MOLLIER DIAGRAM

The general energy equation for a compression of 1 pound of air saturated with water vapor when no liquid is present at the end of compression becomes, similar to equation (B1),

$$H_{a,1} + X_1 H_{g,1} + (X_2 - X_1) H_{f,1} + \Delta H_c = H_{a,2} + X_2 H_{g,2} \quad (B11)$$

For the ideal conditions, the entropy remains constant; therefore

$$S_{a,1} + X_1 S_{g,1} + (X_2 - X_1) S_{f,1} = S_{a,2} + X_2 S_{g,2} \quad (B12)$$

If the enthalpy and the entropy of the excess liquid water are assigned values of zero at a particular temperature and the liquid water is introduced at this temperature, equations (B11) and (B12) become

$$H_{a,1} + X_1 H_{g,1} + \Delta H_c = H_{a,2} + X_2 H_{g,2} \quad (\text{B13})$$

and

$$S_{a,1} + X_1 S_{g,1} = S_{a,2} + X_2 S_{g,2} \quad (\text{B14})$$

In a saturated mixture of air and water vapor, the enthalpy per pound of air is

$$H = H_a + X H_g \quad (\text{B15})$$

and the entropy per pound of air is

$$S = S_a + X S_g \quad (\text{B16})$$

If equations (B15) and (B16) are plotted for a range of temperatures and pressures, the conditions of the mixture resulting from a compression of 1 pound of air that is continually saturated with water vapor may be determined. Equations (B15) and (B16) are the basis for the Mollier diagram presented. The base temperature for enthalpy and entropy of liquid water was chosen as 519° R. Thus, if any liquid water present is assumed to be at 519° R, no correction need be made for the enthalpy and the entropy of the liquid when using the Mollier diagram. The values of enthalpy and entropy were so adjusted that at standard sea-level conditions of temperature of 519° R and pressure of 14.696 pounds per square inch the enthalpy of the saturated mixture of air and water vapor is 100 Btu per pound of air and the entropy is 0.10 Btu/(lb air) (°R). The modified versions of equations (B15) and (B16), which were used in plotting the Mollier diagram, are

$$H = h_a + 60.24 + X(h_g - 27.06) \quad (\text{B17})$$

and

$$S = \phi_a - \frac{R_a}{J} \log_e \frac{(p_m - p_g)}{18.189} + X(s_g - 0.0536) \quad (\text{B18})$$

Values for h_a and ϕ_a were obtained from reference 4 and

are for a base temperature of 400° R; values for h_g and s_g were obtained from reference 5 and are for a base temperature of 32° F (492° R).

The weight ratio of water vapor to air in a saturated mixture may be determined by the relation

$$X = \frac{v_a}{v_g} \quad (\text{B19})$$

When the equation of state and Dalton's law of partial pressures are used, equation (B19) may be written

$$X = \frac{R_a t_a}{(p_m - p_g)(144 v_g)} \quad (\text{B20})$$

Equation (B20) was used for determining values of X for equations (B17) and (B18).

If liquid water is injected at any temperature other than 519° R, the enthalpy and the entropy of the water will not be zero and an error will be introduced when using the Mollier diagram. This error can be corrected by adjusting the initial enthalpy and entropy, as read from the diagram, to include the enthalpy and the entropy of the injected liquid water. The corrected enthalpy and entropy for the initial condition will be

$$H_{corr} = H + (h_f - 27.06)\Delta X \quad (\text{B21})$$

and

$$S_{corr} = S + (s_f - 0.0536)\Delta X \quad (\text{B22})$$

A similar correction, made by subtracting the enthalpy and the entropy of the liquid, can be performed at the end of the process if any liquid water remains. Values of H_f , which is $h_f - 27.06$, and S_f , which is $s_f - 0.0536$, are plotted in an insert on the Mollier diagram for various temperatures.

If liquid water is injected at a temperature different from the initial temperature of the saturated air, a slight increase in entropy occurs because of the mixing of the constituents as a new temperature equilibrium is reached. This increase in entropy may be neglected, however, without introducing appreciable error when using the Mollier diagram.

APPENDIX C

SAMPLE CALCULATIONS

The use of the Mollier diagram in calculating saturated compression processes is illustrated by the following sample calculations:

SAMPLE CALCULATION I

In calculating a compression process for an actual engine, the work input to the compressor is usually obtained on the basis of 1 pound of working fluid passing through the compressor. In order to use the Mollier diagram for a saturated compression process, the work input must be found on a basis of 1 pound of air (the unit on which the Mollier diagram is based). Corrections must also be made for the enthalpy and the entropy of the liquid water when the water injected is not at a temperature of 519° R if it is desired to maintain a high degree of accuracy in using the Mollier diagram. In order to illustrate these refinements, the following example is presented for an engine with a single-stage centrifugal compressor. The following conditions are assumed:

Ambient static temperature, t_0 , °R.....	519
Ambient static pressure, p_0 , lb/sq in.....	14.7
Flight Mach number, M	0.85
Flight velocity, V , ft/sec.....	949
Diffuser adiabatic efficiency, η_d	0.85
Ambient relative humidity, ϕ	0.50
Compressor-rotor-tip velocity, V_T , ft/sec.....	1500
Compressor slip factor, K	0.95
Compressor adiabatic efficiency, η_c	0.80

Enough liquid water is injected at the compressor inlet at a temperature of 540° R to saturate the air at this point and to keep the air saturated during the entire compression process. Find P_2 , T_2 , X_2 , and the amount of water evaporated.

The water-air ratio for saturated conditions at an ambient temperature of 519° R and a pressure of 14.7 pounds per square inch is, from the Mollier diagram,

$$X = 0.0106$$

For a relative humidity of 0.50, the value of X for the ambient air is

$$X_0 = \frac{0.0106}{2} = 0.0053$$

The static-temperature rise in the inlet diffuser due to ram compression is (value of $c_{p,m}$ obtained from fig. 3(a))

$$\Delta t_{(0-1)} = \frac{V^2}{2gJc_{p,m}} = \frac{(949)^2}{(2)(32.2)(778)(0.2416)} = 74.4 \text{ F}^\circ$$

and

$$T_1 = 519 + 74.4 = 593.4^\circ \text{ R}$$

When equation (B17) is evaluated for 593.4° R, the enthalpy at the compressor inlet without taking into account the enthalpy of the liquid water that is injected at this point is

$$\begin{aligned} H_1' &= h_a + 60.24 + X(h_g - 27.06) \\ &= 46.31 + 60.24 + 0.0053(1119.1 - 27.06) \\ &= 112.3 \text{ Btu/lb air} \end{aligned}$$

The compressor-inlet pressure is (γ_m obtained from fig. 3(a))

$$\begin{aligned} P_1 &= p_0 \left[\frac{\eta_d \Delta t_{(0-1)}}{t_0} + 1 \right]^{\frac{\gamma_m}{\gamma_m - 1}} \\ &= 14.7 \left[\frac{(0.85)(74.4)}{519} + 1 \right]^{\frac{1.398}{0.398}} \\ &= 22.0 \text{ lb/sq in.} \end{aligned}$$

When liquid water is injected at the compressor inlet, the temperature decreases but the pressure remains constant, as does the enthalpy if the enthalpy of the injected water is neglected. From the Mollier diagram at an enthalpy of 112.3 Btu per pound of air and a pressure of 22.0 pounds per square inch, the entropy at the compressor inlet, not considering the entropy of the liquid water, is

$$S_1' = 0.0949 \text{ Btu/(lb air)} (^\circ \text{R})$$

This point on the Mollier diagram could also have been determined from P_1 and T_1 where the value of T_1 is obtained from figure 1.

In order to obtain the enthalpy of the mixture in Btu per pound of air at the compressor inlet, correction must be made for the enthalpy of the liquid water that is injected at 540° R, which requires that the amount of water injected for saturation at the compressor outlet be known. Because X_2 is unknown, an approximate value X_2' must be assumed. The following approximation for sea-level pressure was obtained by inspection of calculations for a wide range of ambient-air temperatures, flight Mach numbers, and compressor pressure ratios and may be used to determine X_2' in order to eliminate or to simplify successive approximation methods:

$$X_2' = X_0 + 0.00065 \Delta H_{m,(0-2)} \theta^2$$

The enthalpy rise in the compressor is

$$\begin{aligned} \Delta H_{m,(1-2)} &= \frac{KV_T^2}{gJ} \\ &= \frac{(0.95)(1500)^2}{(32.2)(778)} \\ &= 85.3 \text{ Btu/lb mixture} \end{aligned}$$

and the enthalpy rise in the inlet diffuser is

$$\begin{aligned} \Delta H_{(0-1)} &= c_{p,a} \Delta t_{(0-1)} (1 + X_0) = (0.2416)(74.4)(1.0053) \\ &= 18.1 \text{ Btu/lb air} \end{aligned}$$

Therefore

$$X_2' = 0.0053 + 0.00065(18.1 + 85.3)(1)^2 = 0.0725$$

and

$$\Delta X'_{(0-2)} = 0.0725 - 0.0053 = 0.0672$$

These values will be used for X_2 and $\Delta X_{(0-2)}$ for the rest of the calculations.

From the insert on the Mollier diagram, the enthalpy and the entropy of the liquid water at 540° R are

$$H_f = 21.0 \text{ Btu/lb water}$$

and

$$S_f = 0.04 \text{ Btu/(lb water)} (^\circ\text{R})$$

The enthalpy and the entropy due to the liquid water are then

$$H_{f,1} = \Delta X_{(0-2)} H_f = (0.0672)(21.0) = 1.4 \text{ Btu/lb air}$$

and

$$S_{f,1} = \Delta X_{(0-2)} S_f = (0.0672)(0.04) = 0.0027 \text{ Btu/(lb air)} (^\circ\text{R})$$

The values for enthalpy and entropy at the compressor inlet corrected for the liquid water at a temperature of 540° R are

$$H_{1,corr} = H_1' + H_{f,1} = 112.3 + 1.4 = 113.7 \text{ Btu/lb air}$$

and

$$S_{1,corr} = S_1' + S_{f,1} = 0.0949 + 0.0027 = 0.0976 \text{ Btu/(lb air)} (^\circ\text{R})$$

When the enthalpy rise per pound of mixture in the compressor is known, it must be converted to enthalpy rise per pound of air in order to use the Mollier diagram. This conversion also requires a value for the water-air ratio at the compressor outlet. The ideal enthalpy rise per pound of air in the compressor is

$$\begin{aligned} \Delta H_{i,(1-2)} &= \Delta H_{m,(1-2)} (1 + X_2) \eta_c = (85.3)(1.0725)(0.80) \\ &= 73.2 \text{ Btu/lb air} \end{aligned}$$

and the final enthalpy for an isentropic compression is

$$H_{2,i} = H_{1,corr} + \Delta H_{i,(1-2)} = 113.7 + 73.2 = 186.9 \text{ Btu/lb air}$$

The compressor-outlet pressure P_2 read from the Mollier diagram at an enthalpy of 186.9 Btu per pound of air and an entropy of 0.0976 Btu/(lb air) ($^\circ\text{R}$) is

$$P_2 = 118.7 \text{ lb/sq in.}$$

The actual enthalpy per pound of air at the compressor outlet is

$$\begin{aligned} H_2 &= H_1 + \Delta H_{m,(1-2)} (1 + X_2) = 113.7 + \\ &\quad (85.3 \times 1.0725) = 205.2 \text{ Btu/lb air} \end{aligned}$$

When the Mollier diagram is read at an enthalpy of 205.2 Btu per pound of air and a pressure of 118.7 pounds per square inch, the temperature is

$$T_2 = 663.2^\circ \text{ R}$$

and

$$X_2 = 0.0730$$

This value of X_2 is very close to the approximate value that was used for X_2 and therefore no further correction is necessary. If this value of X_2 differed greatly from the assumed approximate value, it would be advisable to repeat the calculations using the value of X_2 just obtained.

The amount of water injected at the compressor inlet is

$$\Delta X_{(0-2)} = 0.0730 - 0.0053 = 0.0677 \text{ lb water/lb air}$$

In order to show the effect of corrections for liquid-water temperatures other than 519° R, the following table presents values of P_2 , T_2 , and X_2 that were obtained for liquid-water-injection temperatures of 519° R (no correction), 540° R (the sample calculation just completed), and for 620° R; all other conditions remained the same as in the sample calculation:

Temperature of injected water ($^\circ\text{R}$)	Pressure P_2 (lb/sq in.)	Temperature T_2 ($^\circ\text{R}$)	Water-air ratio X_2
519	119.2	662.7	0.0718
540	118.7	663.2	.0730
620	118.0	666.0	.0782

This table shows that, for most limits of accuracy for turbojet-cycle calculations, the enthalpy and the entropy of the liquid water may be neglected in the probable range of injected-water temperature.

SAMPLE CALCULATION II

The following example illustrates the calculation of compressor-outlet conditions when an amount of water less than the amount required for outlet saturation is injected at the compressor inlet.

The following conditions are assumed:

Ambient static temperature, t_0 , $^\circ\text{R}$	519
Ambient static pressure, p_0 , lb/sq in.	14.7
Flight velocity, V , ft/sec.....	0
Ambient relative humidity, ϕ	0.50
Compressor adiabatic efficiency, η_c	0.80
Compressor enthalpy rise, ΔH_c , Btu/lb mixture.....	85.3
Air weight flow, W_a , lb/sec.....	80.5
Water-injection rate at 519° R, lb/sec.....	4.0

From Sample Calculation I,

$$X_0 = 0.0053$$

and by evaluating equation (B17) for 519° R,

$$\begin{aligned} H_0 &= h_a + 60.24 X_0 (h_g - 27.06) \\ &= 28.53 + 60.24 + 0.0053(1087.6 - 27.06) \\ &= 94.4 \text{ Btu/lb air} \end{aligned}$$

From the Mollier diagram at an enthalpy of 94.4 Btu per pound of air and a pressure of 14.7 pounds per square inch, the entropy is

$$S_0 = 0.0890 \text{ Btu/(lb air)} (^\circ\text{R})$$

The change in water-air ratio ΔX due to the addition of the liquid water is

$$\Delta X_{(0-2)} = \frac{4}{80.5} = 0.0497$$

and

$$X_2 = X_0 + \Delta X_{(0-2)} = 0.0053 + 0.0497 = 0.0550$$

If the approximation from Sample Calculation II is used,

$$\Delta H_{m, (0-2)}' = \frac{\Delta X_{(0-2)}}{(0.00065)\theta^2} = \frac{0.0497}{(0.00065)1} = 76.5 \text{ Btu/lb mixture}$$

Using this approximate value of $\Delta H_{m, (0-2)}$ yields

$$\Delta H_{(0-2)}' = \Delta H_{m, (0-2)}'(1 + X_2) = (76.5)(1.0550) = 80.7 \text{ Btu/lb air}$$

Then

$$H_2' = H_0 + \Delta H_{(0-2)}' = 94.4 + 80.7 = 175.1 \text{ Btu/lb air}$$

and

$$H_{2, t}' = H_0 + \Delta H_{(0-2)}' \eta_c = 94.4 + (80.7)(0.80) = 159.0 \text{ Btu/lb air}$$

From the Mollier diagram at an enthalpy of 159.0 Btu per pound and an entropy of 0.0890 Btu per pound per $^{\circ}\text{R}$,

$$P_2' = 73.5 \text{ lb/sq in.}$$

From the Mollier diagram at a pressure of 73.5 pounds per square inch and an enthalpy of 175.1 Btu per pound air,

$$X_2' = 0.0542$$

This value of X_2' is lower than the desired value. If the value of $\Delta H_{m(0-2)}'$ is increased to 77.7 Btu per pound of air and the calculation repeated, the values obtained are

$$P_2 = 75.0 \text{ lb/sq in.}$$

$$X_2 = 0.0550$$

and

$$T_2 = 630.5^{\circ} \text{ R}$$

The rest of the compression process may be calculated as an adiabatic compression of the mixture of air and water vapor using the thermodynamic properties given in figure 3(a). From figure 3(a) at $X=0.0550$,

$$c_{p, m} = 0.2513 \text{ Btu/(lb)} (^{\circ}\text{R})$$

and

$$\gamma_m = 1.3916$$

Then

$$\Delta T_{(2-3)} = \frac{\Delta H_{m(2-3)}}{c_{p, m}} = \frac{(85.3 - 77.7)}{0.2513} = 30.2^{\circ} \text{ F}$$

and

$$\frac{P_3}{P_2} = \left[\left(\frac{\Delta T_{(2-3)}}{T_2} \right) \eta_c + 1 \right]^{\frac{\gamma_m}{\gamma_m - 1}} = \left[\left(\frac{30.2}{630.5} \right) 0.80 + 1 \right]^{\frac{1.3916}{0.3916}} = 1.143$$

The conditions at the compressor outlet are

$$P_3 = \left(\frac{P_3}{P_2} \right) P_2 = (1.143)(75.0) = 85.7 \text{ lb/sq in.}$$

$$T_3 = T_2 + \Delta T_{(2-3)} = 630.5 + 30.2 = 660.7^{\circ} \text{ R}$$

and

$$X_3 = X_2 = 0.0550$$

For a comparison of the effect of the amount of water evaporated on pressure and temperature at the compressor outlet, the results of Sample Calculation I (air saturated up to the compressor outlet for a water-injection temperature of 519° R), and of the cases of air saturated during one-half of the work input to the compressor, of air saturated up to the compressor inlet, and of no injection are shown in the following table:

($M=0.85$; $\Delta H_c=85.3 \text{ Btu/lb mixture}$; $\eta_c=0.80$)

Condition	Amount of water evaporated (lb water/lb air)	Outlet pressure P_3 (lb/sq in.)	Outlet temperature T_3 ($^{\circ}\text{R}$)
No injection.....	0	86.5	947
Air saturated up to compressor inlet.....	.0113	95.4	895
Air saturated through one-half of work input.....	.0384	108.0	778
Air saturated up to compressor outlet.....	.0665	119.2	663

APPENDIX D

EQUATIONS USED IN AUGMENTATION CALCULATIONS

The method of calculating compressor-outlet conditions when water is evaporated during compression is given in the section DISCUSSION OF CHARTS and illustrated in appendix C. The other equations used for the step-by-step calculations of engine performance are:

Inlet diffuser,

$$\frac{P_1}{P_0} = \left(\frac{\eta_d V^2}{2Jg c_{p,m} t_0} + 1 \right)^{\frac{\gamma_m}{\gamma_m - 1}}$$

Compressor (with no evaporation during compression),

$$\frac{P_3}{P_1} = \left(\frac{\eta_c K V_T^2}{T_1 g J c_{p,m}} + 1 \right)^{\frac{\gamma_m}{\gamma_m - 1}}$$

Turbine,

$$\frac{P_5}{P_4} = \left[1 - \frac{\Delta H_{m,c}(1 + X_3)}{\eta_t T_4 (1 + X_3 + f/a) c_{p,e}} \right]^{\frac{\gamma_e}{\gamma_e - 1}}$$

Thrust (for sonic jet velocity),

$$\frac{F}{A_t} = \frac{V_j W_t}{g A_t} + \frac{A_n}{A_t} (p_6 - p_0) - \frac{V W_a}{g A_t} (1 + X_0)$$

where

$$V_j = \sqrt{g \gamma_e R_e t_6}$$

$$t_6 = T_5 \left(\frac{2}{\gamma_e + 1} \right)$$

$$\frac{W_t}{A_t} = \left(\frac{P_4}{\sqrt{T_4 R_e / g \gamma_e}} \right) \left(\frac{2}{1 + \gamma_e} \right)^{\frac{\gamma_e + 1}{2(\gamma_e - 1)}}$$

$$\frac{A_n}{A_t} = \frac{W_t}{A_t} \frac{R_e t_6}{V_j p_6}$$

$$\frac{p_6}{P_5} = \left[1 - \left(\frac{\gamma_e - 1}{\gamma_e + 1} \right) \frac{1}{\eta_n} \right]^{\frac{\gamma_e}{\gamma_e - 1}}$$

and

$$\frac{W_a}{A_t} = \frac{W_t}{A_t} \left(\frac{1}{1 + X_3 + f/a} \right)$$

Thrust (for subsonic jet velocity),

$$\frac{F}{A_t} = V_j \frac{W_t}{g A_t} - \frac{V W_a}{g A_t} (1 + X_0)$$

where

$$V_j = \sqrt{2 \eta_n g R_e \frac{\gamma_e}{\gamma_e - 1} T_5 \left[1 - \left(\frac{p_0}{P_5} \right)^{\frac{\gamma_e - 1}{\gamma_e}} \right]}$$

and W_t/A_t and W_a/A_t are the same as for the case of sonic jet velocity. Values for $c_{p,m}$ and γ_m were obtained from figure 3(a) and values of $c_{p,e}$, R_e , and γ_e from figure 3(b). Values for f/a were obtained from reference 8.

REPORT 1007

HORIZONTAL TAIL LOADS IN MANEUVERING FLIGHT¹

By HENRY A. PEARSON, WILLIAM A. MCGOWAN, and JAMES J. DONEGAN

SUMMARY

A method is given for determining the horizontal tail loads in maneuvering flight. The method is based upon the assignment of a load-factor variation with time and the determination of a minimum time to reach peak load factor. The tail load is separated into various components. Examination of these components indicated that one of the components was so small that it could be neglected for most conventional airplanes; therefore, the number of aerodynamic parameters needed in this computation of tail loads was reduced to a minimum.

In order to illustrate the method, as well as to show the effect of the main variables, a number of examples are given.

Some discussion is given regarding the determination of maximum tail loads, maximum pitching accelerations, and maximum pitching velocities obtainable.

INTRODUCTION

The subject of maneuvering tail loads has received considerable attention both experimentally and theoretically. Theoretically, methods and solutions have been derived for determining the horizontal tail load following either a prescribed elevator motion (references 1 to 3) or an assigned load-factor variation (reference 4).

The first approach has been adopted into some of the load requirements where the type of elevator movement specified consists of linear segments whose magnitudes and rates of movement are governed by the assignment of a maximum initial elevator movement consistent with the pilot's strength. The rates of movement and the time the elevator is held before reversing are so adjusted that the design load factor will not be exceeded.

The results of reference 5 show, as is to be expected, that only when the aerodynamic force coefficients are accurately known from wind-tunnel tests can good agreement be obtained between measured and calculated tail loads. At the design stage, however, only general aerodynamic and geometric quantities are available and some of the more important stability parameters are not known accurately. Thus, the work involved in the solution for the tail load following a given elevator motion is not considered to be in keeping with the accuracy of the results obtained. Consequently, there appears to be a need for an abbreviated

design method of computing tail loads which, although incorporating approximations, will nevertheless be based on the theoretical considerations of the problem.

If the load-factor variation with time is specified and the corresponding tail load, elevator angles, and load distributions are subsequently determined, a simpler and equally rational approach to the tail-load problem can be made. Although this approach has been used to a limited degree (reference 4), several shortcomings have limited its use.

The purpose of this report is to develop further the load-factor or inverse approach and to present a method of computing horizontal tail loads which is comprehensive and generally simple. To this end, (1) the shape of the load-factor curve and the minimum time required to reach the peak load factor have been determined from an analysis of pull-up maneuvers that were available, (2) the minimum time required to reach the peak load factor has been determined from a theoretical analysis which is supported in some measure by statistical data obtained from a number of flight tests with airplanes of widely varying sizes, and (3) the equations relating the various quantities are presented.

SYMBOLS

b	wing span, feet; shape factor in equation (13)
b_t	tail span, feet
c	chord, feet
$\bar{c}$	mean aerodynamic wing chord, feet
C_L	lift coefficient (L/qS)
C_m	pitching-moment coefficient of airplane without horizontal tail (Mb/qS^2)
C_{m_t}	pitching-moment coefficient of isolated horizontal-tail surface
g	acceleration due to gravity, feet per second per second
I	pitching moment of inertia, slug-feet ²
k_r	radius of gyration about pitching axis, feet
K	empirical constant denoting ratio of damping moment of complete airplane to damping moment of tail alone
L	Lift, pounds
l	local lift at any spanwise station
m	airplane mass, slugs (W/g)
M	pitching moment, foot-pounds
n	airplane load factor at any instant

¹ Supersedes NACA TN 2078, "Horizontal Tail Loads in Maneuvering Flight" by Henry A. Pearson, William A. McGowan, and James J. Donegan, 1950.

N	maximum increment in load factor
q	dynamic pressure, pounds per square foot $\left(\frac{1}{2} \rho V^2\right)$
S	wing area, square feet
S_t	horizontal-tail area, square feet
t	time, seconds
t_1	time to reach peak of elevator deflection, seconds
V	airplane true velocity, feet per second
W	airplane weight, pounds
x_t	length from center of gravity of airplane to aerodynamic center of tail (positive for conventional airplanes), feet
y	spanwise dimension, feet
y^*	nondimensional spanwise dimension $\left(\frac{y}{b/2}\right)$
a, b, c	constants occurring in equations (13), (23), (26), and (30)
A, B, C, D, E	
K_1, K_2, K_3	constants occurring in basic differential equation (see equation (3))
λ	time to reach peak load factor, seconds
ρ	mass density of air, slugs per cubic foot
η_t	tail efficiency factor (q_t/q)
α	wing angle of attack, radians
$\bar{\alpha}$	average angle of attack of horizontal stabilizer, radians
α_t	tail angle of attack, radians
β	angle of sideslip, degrees
γ	flight-path angle, radians
θ	attitude angle, radians ($\alpha + \gamma$)
δ	elevator angle, radians
ϵ	downwash angle, radians $\left(\frac{d\epsilon}{d\alpha} \alpha\right)$
i_t	tail setting, radians

The notations $\dot{\alpha}$ and $\dot{\theta}$, $\ddot{\alpha}$ and $\ddot{\theta}$, and so forth, denote single and double differentiations with respect to t .

The symbol Δ represents an increment from the steady-flight datum value.

Subscripts:

0	initial or selected value
t	tail
max	maximum value
l_0	zero lift
geo	geometric
c	camber

METHODS

METHOD OF DETERMINING THE DYNAMIC TAIL LOAD

Basic equations of motion.—The simple differential equations for the longitudinal motion of an airplane for any

elevator deflection (see method given in reference 2) may be written as

$$m\dot{\gamma}V - \frac{dC_L}{d\alpha} \Delta\alpha q S - \left(\frac{dC_L}{d\delta}\right)_t \eta_t q S_t \Delta\delta = 0 \quad (1)$$

$$\frac{dC_m}{d\alpha} \Delta\alpha q \frac{S^2}{b} - \Delta L_t x_t + \frac{dC_{m_t}}{d\delta} \eta_t q \frac{S_t^2}{b_t} \Delta\delta - mk_Y^2 \ddot{\theta} = 0 \quad (2)$$

Equations (1) and (2) represent summations of forces perpendicular to the relative wind and of moments about the center of gravity. (See fig. 1 for direction of positive quantities.) Implicit in these equations are the following assumptions:

(1) In the interval between the start of the maneuver and the attainment of maximum loads, the flight-path angle does not change materially; therefore, the change in load factor due to flight-path change is small.

(2) At the Mach number for which computations are made, the aerodynamic derivatives are linear with angle of attack and elevator angle.

(3) The variation of speed during the maneuver may be neglected.

(4) Unsteady lift effects may be neglected.

By use of the relations $\theta = \gamma + \alpha$, $\dot{\theta} = \dot{\gamma} + \dot{\alpha}$, and $\ddot{\theta} = \ddot{\gamma} + \ddot{\alpha}$, equations (1) and (2) are reducible to the equivalent second-order differential equation

$$\ddot{\alpha} + K_1 \dot{\alpha} + K_2 \Delta\alpha = K_3 \Delta\delta \quad (3)$$

where

$$K_1 = \frac{\rho V}{2m} \left[\frac{dC_{L_t}}{d\alpha_t} \frac{S_t x_t^2}{k_Y^2} \eta_t \left(\frac{K}{\sqrt{\eta_t}} + \frac{d\epsilon}{d\alpha} \right) + \frac{dC_L}{d\alpha} S \right]$$

$$K_2 = -\frac{\rho V^2}{2m} \left\{ \frac{dC_m}{d\alpha} \frac{S^2}{k_Y^2 b} - \frac{dC_{L_t}}{d\alpha_t} \eta_t \frac{S_t x_t}{k_Y^2} \left[\left(1 - \frac{d\epsilon}{d\alpha} \right) + \frac{dC_L}{d\alpha} \frac{K}{\sqrt{\eta_t}} \frac{\rho S x_t}{2m} \right] \right\}$$

and

$$K_3 = \frac{\rho V^2}{2m} \left(-\frac{dC_{L_t}}{d\delta} \eta_t \frac{S_t x_t}{k_Y^2} + \frac{dC_{m_t}}{d\delta} \eta_t \frac{S_t^2}{b_t k_Y^2} - \frac{dC_{L_t}}{d\alpha_t} \frac{dC_{L_t}}{d\delta} \frac{K \eta_t^2}{\sqrt{\eta_t}} \frac{\rho x_t^2 S_t^2}{2m k_Y^2} \right)$$

In equations (1) and (2), $\Delta\alpha$, $\dot{\gamma}$, $\ddot{\theta}$, $\Delta\delta$, and ΔL_t will, in a given maneuver, vary with time. Using the relations between θ , γ , α , and their derivatives permits equation (2) to be rewritten as follows to give the increment in tail load:

$$\Delta L_t = \frac{dC_m}{d\alpha} \Delta\alpha q \frac{S^2}{b x_t} - \frac{mk_Y^2 \ddot{\alpha}}{x_t} - \frac{mk_Y^2 \ddot{\gamma}}{x_t} + \frac{dC_{m_t}}{d\delta} \eta_t q \frac{S_t^2}{b_t x_t} \Delta\delta \quad (4)$$

FIGURE 1.—Sign conventions employed. Positive directions shown.

In a still shorter form, equation (4) may be written as

$$\Delta L_t = \Delta L_{t_\alpha} + \Delta L_{t_{\ddot{\alpha}}} + \Delta L_{t_{\ddot{\gamma}}} + \Delta L_{t_\epsilon} \quad (5)$$

Equations (4) and (5) show that the tail-load increment (the increment above the steady-flight datum value) at any time is composed of four parts: ΔL_{t_α} , associated with the angle-of-attack change; $\Delta L_{t_{\ddot{\alpha}}}$, associated with angular acceleration about the flight path; $\Delta L_{t_{\ddot{\gamma}}}$, associated with angular acceleration of the flight path; and ΔL_{t_ϵ} , required to compensate for the moment introduced by change in camber of the horizontal-tail surface. The load ΔL_{t_ϵ} is generally small but in some extreme configurations may amount to 10 percent of the total increment and thus, for the present, it is retained in the development.

If the load-factor-increment variation with time Δn is known, then by the usual definition

$$\Delta n = \frac{dC_L}{d\alpha} \Delta \alpha \frac{q}{W/S} \quad (6)$$

so that

$$\Delta \alpha = \frac{\Delta n W/S}{\frac{dC_L}{d\alpha} q}$$

$$\dot{\alpha} = \frac{\dot{n} W/S}{\frac{dC_L}{d\alpha} q}$$

and

$$\ddot{\alpha} = \frac{\ddot{n} W/S}{\frac{dC_L}{d\alpha} q}$$

The following relation also exists between Δn and $\dot{\gamma}$:

$$\Delta n g = \dot{\gamma} V \quad (7)$$

so that

$$\ddot{\gamma} = \frac{\dot{n} g}{V} \quad (8)$$

When equations (6) and (8) are substituted into equations (4) and (5), the four tail-load components then become

$$\Delta L_{t_\alpha} = \frac{dC_m}{dC_L} \frac{W S}{b x_t} \Delta n \quad (9a)$$

$$\Delta L_{t_{\ddot{\alpha}}} = - \frac{W^2 k_Y^2}{g S q x_t} \frac{dC_L}{d\alpha} \ddot{n} \quad (9b)$$

$$\Delta L_{t_{\ddot{\gamma}}} = - \frac{W k_Y^2}{V x_t} \dot{n} \quad (9c)$$

$$\Delta L_{t_\epsilon} = \frac{dC_{m_t}}{d\delta} \eta_t q \frac{S_t^2}{b_t x_t} \Delta \delta \quad (9d)$$

Thus, if the variation of the load factor with time Δn and the geometric and aerodynamic characteristics of the airplane were known, the first three components of the tail load could be found immediately. The magnitude of the fourth component, that due to horizontal-tail camber, would follow from equation (3) in which the elevator angle is seen to be

$$\Delta \delta = \frac{\ddot{\alpha}}{K_3} + \frac{K_1}{K_3} \dot{\alpha} + \frac{K_2}{K_3} \Delta \alpha \quad (10)$$

Substitution into equation (10) of the values of $\Delta \alpha$, $\dot{\alpha}$, and $\ddot{\alpha}$ from equation (6) yields the value of the elevator angle at any instant

$$\Delta \delta = \frac{W/S}{K_3 \frac{dC_L}{d\alpha} q} (\ddot{n} + K_1 \dot{n} + K_2 \Delta n) \quad (11)$$

so that, finally, the fourth component is given as

$$\Delta L_{t_\epsilon} = \frac{dC_{m_t}}{d\delta} \eta_t \frac{S_t^2}{b_t x_t} \frac{W/S}{\frac{dC_L}{d\alpha} K_3} (\ddot{n} + K_1 \dot{n} + K_2 \Delta n) \quad (12)$$

The procedure outlined shows that the tail-load magnitude can be determined if the load-factor variation is known.

Types of load-factor variation.—The relation between the tail load, the geometric and aerodynamic characteristics,

and the load factor having been established, it is desirable to establish a load-factor variation which is reasonable as well as critical insofar as loads are concerned. The maximum value of load factor is usually specified; however, there are many possible variations for the shape. Regardless of the details of shape, the load factor may be considered to rise smoothly and continuously to a maximum, the rate of rise depending upon several variables. Beyond the maximum value of the load factor the return to initial conditions can, at the will of the pilot, be either gradual or rapid.

Experiments as well as theoretical studies have already indicated that the maneuver that combines maximum angular and linear accelerations causes critical loads in both the wing and tail. One such maneuver occurs when the maximum load factor is reached as rapidly as possible by using an initial elevator movement which is greater than that required to reach a given steady-trim value of the load factor. This initial elevator movement is followed by a rapid checking of the maneuver either by returning the elevator quickly to neutral or by reversing the controls.

The shape of the load-factor curve for such a maneuver may be expressed approximately by several analytic functions, one of which is

$$\Delta n = at^b e^{-ct} \quad (13)$$

By way of illustration, figure 2 shows details of the shape of the load-factor curve obtained with the use of equation (13) for which the constants have been adjusted so that an 8g peak is reached in 1 second. By further adjustment of the constants the load factor can, within certain limits, be made to rise to any specified peak and to diminish in any prescribed manner.

Because the positive slopes obtained from equation (13) are always greater than the negative slopes, the positive angular accelerations are greater than the negative ones. In general, this condition is true for most high g critical maneuvers performed by most classes of airplanes, but maneuvers may occasionally be performed for which the reverse may be true, particularly for small airplanes.

FIGURE 2.—Variation of load-factor increment. $\Delta n = 8(t)^{1/2} e^{-(t-1)}$.

Determination of constants.—From equations (9), (11), and (12) the required quantities relating to load factor are seen to be Δn , $\dot{n}$, and $\ddot{n}$. Since the increment Δn is to be given by

$$\Delta n = at^b e^{-ct} \quad (13)$$

then at maximum load factor

$$\dot{n} = 0 = \Delta n \left(\frac{b}{t} - c \right) \quad (14)$$

Thus $t = \frac{b}{c}$ at maximum load factor. Let $N = \Delta n_{max}$. Then

$$N = a \left(\frac{b}{c} \right)^b e^{-b} \quad (15)$$

so that

$$\frac{\Delta n}{N} = \left(\frac{t}{b/c} \right)^b e^{b - ct} \quad (16)$$

Let $\frac{b}{c} = \lambda$. Then

$$\frac{\Delta n}{N} = \left(\frac{t}{\lambda} \right)^b e^{b(1 - \frac{t}{\lambda})} \quad (17)$$

Equation (17) is in nondimensional form where λ is the time to reach the peak load factor and b is a constant.

When equation (17) is differentiated, the first and second derivatives become

$$\frac{\dot{n}\lambda}{N} = \frac{\Delta n}{N} b \left(\frac{1}{t/\lambda} - 1 \right) \quad (18)$$

and

$$\frac{\ddot{n}\lambda^2}{N} = \frac{\Delta n}{N} b^2 \left[\frac{\lambda^2}{t^2} \left(1 - \frac{1}{b} \right) - \frac{2\lambda}{t} + 1 \right] \quad (19)$$

In equations (17) to (19) the quantities N , λ , and b are now required in order to determine the variation of Δn , $\dot{n}$, and $\ddot{n}$. The value of N is immediately available from the required maneuver load factor; whereas the time to reach the peak load factor λ can be obtained from examination of available records or by specification. The constant b , as may be seen from equation (17), can best be described as a "shape" factor and has no particular physical significance.

The values of λ and b should be associated with a maneuver which produces maximum tail loads; therefore, the time λ to reach peak load factor should be the minimum possible consistent with possible pilot action and airplane response. The shape factor b should also be consistent with both of these.

In connection with the determination of the minimum time to reach peak load factor, the results shown in figure 3 for a typical airplane are informative. Figure 3 (a) shows the load-factor variation following several abrupt jump elevator movements. The load factor varies with the elevator position, but the time to reach peak load factor does not. Figure 3 (b) shows the load-factor variation for several abrupt hat-shape elevator impulses. Again the load factor is seen to

FIGURE 3.—Incremental-load factor variations following control movement.

vary with the amount of elevator deflection but the time to reach the peak value remains constant. Although the time to reach the peak load factor shown in figure 3 (b) remains constant, it is seen to be less than that shown in the previous case; therefore, an impulse elevator motion produces a smaller value of λ than the jump type.

Because of inertia and elasticity in the control system, the pilot cannot move the elevator instantaneously but requires some finite time t_1 to do so. A possible critical type of elevator impulse thus appears to be one which increases linearly to maximum and decreases at the same rate to zero. In order to determine the minimum time to reach peak load factor associated with such a variation, the equation of motion (equation (3)) has been solved for the triangular elevator impulse for airplanes of various static stabilities and damping.

The results of the computations are given in figure 4 in which the minimum time λ to reach peak load factor is plotted against the time t_1 required to deflect the elevator.

For completeness the curves of figure 4 are labeled for the actual values of K_2 employed in the computation as well as for relative values of stability. By a series of computations the damping term K_1 was found, as was to be expected,

FIGURE 4.—Variation of λ with t_1 .

to have only a secondary effect on λ . The curves apply to an average value of the damping constant. The upper curve, labeled "low stability," should be associated with rearward center-of-gravity positions (that is, low static margin) in combination with one or both of the following: low dynamic pressure or heavy airplanes. The lower curve, labeled "high stability," would be associated with forward center-of-gravity positions in combination with one or both of the following: high dynamic pressure or light airplanes. It is seen that λ increases almost linearly with t_1 and also increases when the restoring forces are reduced, that is, when the stability is reduced.

A preliminary value of the shape factor b (required in equations (17) to (19)) was initially determined from flight records of typical impulse maneuvers by fitting curves of the type given by equation (13) through several points of the actual time histories and determining the constants. The results of this first step were then modified by the results of the same computations which had been made to determine λ , and the variation of b with t_1 given in figure 5 was obtained. Since the b factor is not found to be critical, an average value of 5.0 is suggested, although as a refinement the values from figure 5 may be used.

FIGURE 5.—Variation of shape factor b with t_1 .

The question of the value of t_1 to use is one which must be solved either from experience or from a knowledge of the characteristics of the controls and the control system. For conventional airplanes having the usual amounts of boost and no rate restrictors, the following values of t_1 are suggested as representative:

	t_1
Fighters or small civil airplanes with weight limit from about 500 to 12,000 pounds, seconds.....	0.20
Two-engine airplanes with weight limit from 25,000 to 45,000 pounds, seconds.....	0.25
Four-engine airplanes with weight limit from 50,000 to 80,000 pounds, seconds.....	0.30
Airplanes with weight limit above 100,000 pounds, seconds.....	0.40

The minimum time λ given in figure 4 was actually established separately from the adopted load-factor variation; therefore, in applying the inverse method, the derived elevator impulse would not be expected to agree in detail with the "tent" type impulse used in the derivation.

The first three tail-load components can now be computed by inserting the values of Δn , $\dot{n}$, and $\ddot{n}$ from equations (17) to (19) into equation (9) and using appropriate values of λ from figure 4. In order to facilitate this computation, curves of $\Delta n/N$, $\dot{n}\lambda/N$, and $\ddot{n}\lambda^2/N$ plotted against t/λ are given in figure 6 for the suggested value of $b=5$. Actually, in order to apply the results of figure 6 it is convenient to find first the components ΔL_{t_a} , and so forth, in terms of the nondimensional time t/λ and then to convert to time t in seconds. In order either to compute the fourth component or to obtain the elevator angles for use in chord loading, the constants K_1 , K_2 , and K_3 of equation (3) must also be known.

Thus, in terms of t/λ and the ordinates of figure 6, the various tail-load components are

$$\Delta L_{t_a} = \frac{dC_m}{dC_L} \frac{WSN}{bx_i} \quad (\text{Ordinate of fig. 6(a)}) \quad (20a)$$

$$\Delta L_{t_{\ddot{a}}} = \frac{-W^2 k_Y^2}{gSq x_i} \frac{N}{dC_L} \frac{1}{\lambda^2} \quad (\text{Ordinate of fig. 6(c)}) \quad (20b)$$

$$\Delta L_{t_{\dot{a}}} = \frac{-Wk_Y^2}{Vx_i} \frac{N}{\lambda} \quad (\text{Ordinate of fig. 6(b)}) \quad (20c)$$

$$\Delta L_{t_c} = \frac{dC_{m_t}}{d\delta} \eta_i \frac{S_i^2}{b_i x_i} \frac{W}{S} \frac{N}{K_3} \frac{dC_L}{d\alpha} \left[\frac{\text{Ordinate of fig. 6(c)}}{\lambda^2} + \frac{K_1(\text{Ordinate of fig. 6(b)})}{\lambda} + K_2(\text{Ordinate of fig. 6(a)}) \right] \quad (20d)$$

The constants K_1 , K_2 , and K_3 defined previously herein are the same as those given in reference 2, except for changed signs caused by specifying x_i as positive.

The conversion to time t is made by multiplying values of the base scale t/λ by λ .

Sample calculations for incremental tail loads.—The results of several examples are given to illustrate not only the method but also the effect of each of a number of variables on the incremental tail load of a fighter-type airplane, the geometric and aerodynamic characteristics of which are given in table I. In order to illustrate the effect of static stability, results have been computed for three center-of-gravity positions with the assumption that an 8g recovery is made at 19,100 feet from a vertical dive at an airspeed of 400 miles per hour. In order to illustrate the effect of the time of the elevator impulse on the tail load, computations were carried out at one of the center-of-gravity positions for several values of t_1 . The cases considered and the airplane characteristics are given in table I.

TABLE I.—AIRPLANE CHARACTERISTICS

(a) Geometric.	
Gross wing area, S , square feet.....	300
Gross horizontal-tail area, S_i , square feet.....	60
Airplane weight, W , pounds.....	12,000
Wing span, b , feet.....	41
Tail span, b_i , feet.....	16
Radius of gyration, k_Y , feet.....	6.4
Distance from aerodynamic center of airplane less tail to aerodynamic center of tail, x_i , feet:	
Center of gravity, 29 percent M. A. C.....	20.0
Center of gravity, 24 percent M. A. C.....	20.3
Center of gravity at aerodynamic center.....	21.0
(b) Aerodynamic.	
Slope of airplane lift curve, $dC_L/d\alpha$, radians.....	4.87
Slope of tail lift curve, $dC_{L_i}/d\alpha_i$, radians.....	3.15
Downwash factor, $d\epsilon/d\alpha$	0.54
Tail efficiency factor (q_i/q), η_i	1.00
Empirical airplane damping factor, K	1.1
Elevator effectiveness factor, $dC_{L_i}/d\delta$, radians.....	1.89
Rate of change of tail moment with camber due to elevator angle, $dC_{m_i}/d\delta$, radian.....	-0.57
Rate of change of moment coefficient with angle of attack for airplane less tail, $dC_{m_t}/d\alpha$, radians:	
Center of gravity, 29 percent M. A. C.....	0.625
Center of gravity, 24 percent M. A. C.....	0.403
Center of gravity at aerodynamic center.....	0.000

FIGURE 6.—Variation of incremental-load-factor curves with time ratio.

The specified conditions for the sample computations are given in table II. The computed results for tail components are given in figures 7 and 8. Figure 7 gives results for varying the center of gravity and figure 8 gives similar results for varying t_1 . The tail-load components are computed from equations (20) and the derived elevator angles from equation

(11). If the increment in tail load due to camber and the incremental elevator angle are not required, the values of K need not be computed and the computations are considerably shortened. Figures 7 and 8 show that a maximum error of only about 4 percent is introduced by this omission.

FIGURE 7.—Effect of center-of-gravity position on incremental-tail-load components.

TABLE II.—SPECIFIED CONDITIONS OF SAMPLE PROBLEM

Increment in load factor.....	8.0
Altitude, feet.....	19,100
Air density, slug per cubic foot.....	0.001306

Case	c. g. (percent M. A. C.)	t_1	K_1	K_2	K_3	λ (fig. 4)
1	a. c.	0.2	4.93	30.4	-33.4	0.45
2	24	.2	4.72	16.2	-32.2	.50
3	29	.2	4.61	8.45	-31.7	.56

METHOD OF DETERMINING THE TOTAL TAIL LOAD

The initial or steady-flight tail load and elevator angles to which the computed incremental values are to be added

must also be determined. In steady flight, the horizontal tail furnishes the moment required to balance the moments from all other parts of the airplane so that the initial load may be written as

$$L_{t_0} = \frac{C_{m_0} q S c}{x_t} + \frac{dC_m}{dC_L} \frac{WS}{bx_t} \cos \gamma_0 \quad (21)$$

Thus the total tail load at any time in a maneuver is composed of the four previously mentioned parts plus the components given in equation (21). Only the first term of equation (21) represents a new type of load because the second term is a load of the type given by equation (9a) or equation (20a) and its effect may be immediately included in the computations by multiplying the ordinates of figure 6 by $N + \cos \gamma_0$ instead of by N .

FIGURE 8.—Effect of t_1 on incremental-tail-load components. Center of gravity, 0.24 $\bar{c}$.

The initial elevator angle required to balance the airplane in steady flight varies with airplane C_L and center-of-gravity position so that, in general, δ_0 must be obtained from wind-tunnel data. Without results of wind-tunnel tests, a rough rule which can be used as a guide at the design stage in determining the elevator position is that the final elevator setting will be so adjusted by repositioning of the stabilizer setting during acceptance tests that it will be near a zero position at the cruising speed and at the most prevalent center-of-gravity position.

METHOD OF DETERMINING MAXIMUM VALUES

Maximum tail loads and angular accelerations.—The method outlined enables a point-by-point evaluation to be made of the quantities that determine the tail load. Such detail may often be unnecessary and the procedure may be shortened by evaluating only those points near the load peaks or, alternatively, by accepting an approximation to the results. One such approximation which may be made is to balance the airplane at the combinations of load factor and angular acceleration which would result in maximum up and down tail loads.

Figure 7 shows that the maximum down tail load in a pull-up occurs near the start of the maneuver and before appreciable load factor is reached. This maximum load is practically coincident with the negative maximum in the $L_{t\alpha}$ tail-load component. Since, for a given configuration, this component increases as the center of gravity is moved forward and since the steady-flight down load increases with speed, the maximum down tail load in a pull-up occurs at the highest design speed in combination with the most forward center-of-gravity position.

Figures 7 and 8 show that at the time of the maximum down-tail-load increment the elevator is near but has not quite reached its peak position. Also at the time of maximum up-tail-load increment the elevator is near its zero position, although it may be on either side of this position depending upon the stability and the time t_i . These results suggest that the maximum down load for the elevator and the hinge brackets would occur with the airplane center of gravity well forward and at the start of the maneuver. The maximum load for the stabilizer is likely to occur at the peak load factor.

Figure 7 also shows that the up tail load occurs near the peak of the component $L_{t\alpha}$ as well as near the positive maximum peak in the component $L_{t\alpha}$. Since the component $L_{t\alpha}$ increases as the center of gravity is moved rearward and since a decrease in speed generally reduces the initial down load, the maximum up tail load occurs at the upper left-hand corner of the V - n diagram for the most rearward center-of-gravity position.

The maximum tail load in a pull-up maneuver may be written as

$$L_{t_{max}} = \frac{C_{m0}qSc}{x_t} + \frac{dC_m}{dC_L} \frac{WS}{bx_t} (n + \cos \gamma_0) - \frac{I\ddot{\theta}}{x_t} \quad (22)$$

where the sum of the second and third terms is to be a maximum in the maneuver. From the previous discussion

the load-factor increment at maximum down load is nearly zero and at maximum up load it is nearly equal to N so that if the positive and negative values of $\ddot{\theta}_{max}$ can be determined, a relatively simple method for determining maximum loads is available.

Since by definition $\ddot{\theta} = \ddot{\alpha} + \ddot{\gamma}$, an expression for angular acceleration can be derived from equations (6) and (7) and written in the form

$$\ddot{\theta} = \frac{W/S}{C_{L\alpha}q} \ddot{n} + \frac{g}{V} \dot{n}$$

The maximum angular acceleration can be approximated by

$$\ddot{\theta}_{max} = B \frac{W/S}{\frac{dC_L}{d\alpha} q} \frac{N}{\lambda^2} + C \frac{gN}{V\lambda} \quad (23)$$

For the maximum positive pitching acceleration, B is the maximum positive ordinate in figure 6 (c) and C is the ordinate of figure 6 (b) at a value of t/λ for which B was determined. Thus, B is 6.5 and C is 0.95 for this example.

For the maximum negative pitching acceleration, B is the maximum negative ordinate in figure 6(c) and C is the ordinate of figure 6(b) at a value of t/λ for which B was determined. Thus, B is -5.8 and C is 0.80. For use in equation (23) the values of λ for the maneuver are available from figure 4 and the other quantities are available from the conditions of the problem. The maximum loads can be given by the following equations:

For maximum up tail load in the pull-up:

$$L_{t_{max+}} = \frac{C_{m0}qSc}{x_t} + \frac{dC_m}{dC_L} \frac{WS}{bx_t} (N + 1.0) + \frac{I_Y N}{x_t \lambda} \left(\frac{5.8W/S}{\frac{dC_L}{d\alpha} q \lambda} - \frac{0.8g}{V} \right) \quad (24a)$$

For maximum down tail load in the pull-up:

$$L_{t_{max-}} = \frac{C_{m0}qSc}{x_t} + \frac{dC_m}{dC_L} \frac{WS}{bx_t} \cos \gamma - \frac{I_Y N}{x_t \lambda} \left(\frac{6.5W/S}{\frac{dC_L}{d\alpha} q \lambda} + \frac{0.95g}{V} \right) \quad (24b)$$

For push-downs to limit load factor, equations (24a) and (24b) still apply with changed signs for N and changed directions for $L_{t_{max+}}$ and $L_{t_{max-}}$. A question arises as to whether the maximum down tail load at the start of a pull-up with forward center-of-gravity position is greater than that which would occur when pulling up from a negative load-factor condition with the center of gravity in the most rearward position. This can be determined only by computing both cases and seeing which is the larger.

Maximum value of angular velocity.—The maximum value of the pitching angular velocity in the pull-up may also be found in a manner similar to that used to obtain the maximum angular acceleration. Since $\dot{\theta} = \dot{\alpha} + \dot{\gamma}$ and the relations involving these quantities in terms of load factor

are given by equations (6) and (7), the following equation may be written:

$$\dot{\theta} = \frac{nW/S}{dC_L} + \frac{\Delta n}{V} \frac{g}{q} \quad (25)$$

The maximum angular velocity may be approximated by

$$\dot{\theta} = D \frac{N}{\lambda} \frac{W/S}{dC_L} + E \frac{Ng}{V} \quad (26)$$

where D is the maximum positive ordinate in figure 6 (b) and E is the ordinate of figure 6 (a) at a value of t/λ for which D was determined. Thus D , for this example, is 1.95 and E is 0.48.

In the steady turn or pull-up at constant g , the angular velocity is usually given by the expression $\dot{\theta} = 1.0 \frac{gN}{V}$. The difference between the factor 1.0 of this expression and the factor 0.48 of equation (26) is more than made up by the angle-of-attack component of the angular velocity.

APPROXIMATE METHOD OF DETERMINING LOAD DISTRIBUTION

Symmetrical loading.—The spanwise distribution of the total load can be formulated with various degrees of exactness. If information regarding details of the angle-of-attack distribution across the span were available, then an exact solution could be obtained for the loading with the use of existing lifting-surface methods. The following method may be used as a first approximation to the solution.

From the total tail load, the total tail lift coefficient C_{L_t} can readily be found. The average effective angle of attack $\bar{\alpha}$ of the stabilizer portion is given in the definition

$$C_{L_t} = \int_0^1 c_{l_\alpha} \bar{\alpha} \frac{c}{c} dy^* + \int_0^1 c_{l_\delta} (\delta_0 + \Delta\delta) \frac{c}{c} dy^* \quad (27)$$

where only $\bar{\alpha}$ is assumed as unknown and c_{l_α} and c_{l_δ} may be taken as the rates of change of section lift coefficient with α and δ , respectively.

Thus, for constant elevator angle across the span,

$$\bar{\alpha} = \frac{C_{L_t} - (\delta_0 + \Delta\delta) \int_0^1 c_{l_\delta} \frac{c}{c} dy^*}{\int_0^1 c_{l_\alpha} \frac{c}{c} dy^*} \quad (28)$$

In a practical case both integrals in equation (28) need be evaluated only once for a given configuration and Mach number. A plot of $\bar{\alpha}$ against C_{L_t} with δ as a parameter would be useful in further computations. With $\bar{\alpha}$ known as a function of C_{L_t} and δ , the local lift at any spanwise station is then obtained from the expression

$$l = c_{l_t} q c = [c_{l_\alpha} \bar{\alpha} + c_{l_\delta} (\delta_0 + \Delta\delta)] q c \quad (29)$$

Unsymmetrical loading.—Up to this point the total loads have been assumed to be symmetrical about the airplane center line, whereas, in reality, the load may have an unsymmetrical part. The sources of this dissymmetry may be due to uneven rigging, differences in elasticity between the two sides, or to effects of slipstream, rolling, and sideslip. The first two sources are usually inadvertent ones while the last two are difficult to determine without either wind-tunnel tests or a knowledge of how the airplane will be operated. Present design rules regarding dissymmetry of tail load are concerned more with providing adequate design conditions for the rear of the fuselage than with recognizing that at the maximum critical tail load some dissymmetry may exist.

Tests in the Langley full-scale tunnel (reference 6) and flight tests (reference 7) of a fighter-type airplane, as well as unpublished flight tests of another fighter-type airplane, indicate that the tail-load dissymmetry varies linearly with angle of sideslip so that the difference in lift coefficient between the two sides of the tail can be given as

$$C_{L_{Right}} - C_{L_{Left}} = A\beta \quad (30)$$

The average values of A per degree found for the two fighter-type airplanes are approximately 0.01. No similar values are available for larger airplanes nor for tail surfaces having appreciable dihedral.

In maneuvers of the type considered herein it is doubtful that angles of sideslip larger than 3° would be developed at the time the maximum tail load is reached. If the value of the sideslip angle at the time of maximum tail load can be established, equations (27) to (29) are easily modified to include this effect, provided that the approximate value of A is known.

Chordwise loading.—The chordwise distribution can be determined for any one spanwise station in either of two ways. One way for design work is outlined in reference 8. A knowledge of the airfoil section and the quantities contained in equation (29) suffices for this determination.

If pressure-distribution data are available for a similar section with flaps, an alternative way would be to distribute the load chordwise according to the two-dimensional pressure diagrams with the use of the computed values of section lift coefficient and elevator angle.

DISCUSSION

The method presented is another approach to the determination of tail loads. From the results given in figures 7 and 8, it can be seen that the camber component L_c is so small that for all practical cases it may be omitted with considerable simplification in the computation of tail loads. This omission reduces to a minimum the number of aerodynamic parameters needed to compute the tail loads.

It is possible, in the application of the present method with the use of the suggested values of t_1 , that the derived elevator angles may not be within the pilot's capabilities. Since it must be assumed that all airplanes, to be satisfactory, should have sufficient control to reach their design load boundaries, such an occurrence requires only that the time to reach elevator peak deflection t_1 be increased so as to reduce the elevator angle. The results of figure 8, in which the time t_1 is varied, furnish a useful guide for determining the increase t_1 that might be required.

If sufficient information is available, it is recommended that existing lifting-surface methods be used in determining the spanwise distribution of the total load; however, if information of the angle-of-attack distribution across the span is not known, the method presented may be used as a first approximation.

Along some of the boundaries of the V - n diagram tail buffeting may occur. Measurements show that buffeting usually occurs along the line of maximum lift coefficient and again along a high-speed buffet line which is associated with a compressibility or force break on some major part of the airplane. All airplanes are subject to buffeting at the design conditions associated with the left-hand corner of the V - n diagram. Only high-speed or high-altitude airplanes or both are capable of reaching the other boundary. Measurements show that the oscillatory buffeting loads may be so high that the designer should at least be cognizant of them at the design stage.

The maximum angular acceleration varies inversely with airspeed and directly with the load factor with the contribution due to acceleration in angle of attack likely to be more important than the angular acceleration of the flight path. A somewhat similar variation is indicated for the maximum angular velocity (equation (26)) where it is seen by direct substitution that the part due to angle of attack is likely to be larger than the part due to the angular velocity of the flight path.

CONCLUDING REMARKS

A simple method has been presented for determining the horizontal tail loads in maneuvering flight with the use of a prescribed incremental load-factor variation.

The incremental tail load was separated into four components representing α , $\ddot{\alpha}$, $\dot{\gamma}$, and c . The camber component L_{t_c} is so small that for most conventional airplanes it may be neglected; therefore, the number of aerodynamic parameters needed in this computation of tail loads was reduced to a minimum.

An approximate method is presented for predicting maximum angular accelerations and maximum angular velocities.

The method indicates that maximum tail loads in a pull-up occur at forward center-of-gravity positions and early in the maneuver. The maximum down tail loads in a pull-up occur at the highest design speed in combination with the most forward center-of-gravity position. The maximum up tail load occurs at the upper left-hand corner of the V - n diagram for the most rearward center-of-gravity positions.

REPORT 1008

A SMALL-DEFLECTION THEORY FOR CURVED SANDWICH PLATES¹

By MANUEL STEIN and J. MAYERS

SUMMARY

A small-deflection theory that takes into account deformations due to transverse shear is presented for the elastic-behavior analysis of orthotropic plates of constant cylindrical curvature with considerations of buckling included. The theory is applicable primarily to sandwich construction.

INTRODUCTION

The usual sandwich plate as used in aircraft construction consists of a light-weight, low-stiffness core material bonded or riveted between two high-stiffness cover sheets. The elastic behavior of such plates under loading cannot be analyzed by conventional plate and shell theories in general since these theories neglect deformations due to transverse shear, an effect which may be of great importance in sandwich construction.

Many authors have considered transverse shear deflections in analyzing the elastic behavior of flat sandwich plates by means of small-deflection theories (see, for example, references 1 to 4). Most of this work has been concerned with sandwich plates of the isotropic type (for example, Metalite, cellular-cellulose-acetate core). In reference 3, however, sandwich plates of the orthotropic type are also considered (for example, corrugated core).

The treatment of curved sandwich plates in the literature has not been as general as that accorded flat sandwich plates, although several specific studies of the curved isotropic sandwich plate have been published. These studies have covered (a) simply supported, slightly curved isotropic sandwich plates under compressive end loading (reference 1), (b) axially symmetric buckling of a simply supported isotropic sandwich cylinder in compression (reference 1), and (c) a nonbuckling small-deflection theory for isotropic sandwich shells which takes into account not only deflections due to shear but also the effects of core compression normal to the faces (reference 5).

The need for a general theory for curved sandwich plates which is applicable to orthotropic as well as isotropic types and which includes both nonbuckling and buckling effects has led to the development of the theory presented in this report. This theory, which takes into account deflections due to

transverse shear, covers those types of sandwich plates having constant cylindrical curvature, similar properties on the average above and below the middle surface, and essentially constant core thickness.

SYMBOLS

D_s	flexural stiffness of isotropic sandwich plate, inch-pounds $\left(\frac{E_s t_s h^2}{2(1-\mu^2)}\right)$
D	flexural stiffness of ordinary plate, inch-pounds $\left(\frac{Et^3}{12(1-\mu^2)}\right)$
D_x, D_y	flexural stiffnesses of orthotropic plate in axial and circumferential directions, inch-pounds
D_{xy}	twisting stiffness of orthotropic plate in xy -plane, inch-pounds
D_{Q_x}, D_{Q_y}	transverse shear stiffnesses of orthotropic plate in axial and circumferential directions, pounds per inch
D_Q	transverse shear stiffness of isotropic sandwich plate, pounds per inch
E	Young's modulus for ordinary plate, pounds per square inch
E_s	Young's modulus for faces of isotropic sandwich plate, pounds per square inch
E_x, E_y	extensional stiffness of orthotropic plate in axial and circumferential directions, pounds per inch
G_{xy}	shear stiffness of orthotropic plate in xy -plane, pounds per inch
$L_E, L_E^{-1}, L_D, \nabla^2, \nabla^4, \nabla^{-4}$	mathematical operators defined in section entitled "Theoretical Derivations"
M_x, M_y	bending moments on plate cross sections perpendicular to x - and y -axes, respectively, inch-pounds per inch
M_{xy}	twisting moments on cross sections perpendicular to x - and y -axes, inch-pounds per inch
N_x, N_y	resultant normal forces in x - and y -directions, pounds per inch
N_{xy}	resultant shearing force in xy -plane, pounds per inch
q	lateral loading, pounds per square inch

¹ Supersedes NACA TN 2017, "A Small-Deflection Theory for Curved Sandwich Plates" by Manuel Stein and J. Mayers, 1950.

Q_x, Q_y	resultant shearing forces in yz -plane and xz -plane, respectively, pounds per inch
h	depth of isotropic sandwich plate measured between middle surfaces of faces, inches
r	constant radius of curvature of plate, inches
t	thickness of ordinary plate, inches
t_s	thickness of face of isotropic sandwich plate, inches
u, v, w	displacements in x -, y -, z -directions, respectively, of a point in middle surface of plate, inches
x, y, z	rectangular coordinates
γ_{xy}	shear strain in xy -plane
ϵ_x, ϵ_y	normal strains in axial and circumferential directions
μ	Poisson's ratio for ordinary plate
μ_x, μ_y	Poisson's ratios for orthotropic plate, defined in terms of curvatures
μ'_x, μ'_y	Poisson's ratios for orthotropic plate, defined in terms of normal strains

THEORETICAL DERIVATIONS

GENERAL THEORY

In developing the equations of equilibrium for the orthotropic curved plate element, shown in figure 1, the basic assumptions made are that the materials are elastic, that the deflections are small compared with the plate thickness, and that the thickness is small compared with the radius of curvature. The last assumption implies that the shear forces N_{xy} and N_{yx} are equal and that the twisting moments M_{xy} and M_{yx} are equal.

Eleven basic equations.—As in ordinary curved-plate theory, 11 equations exist for orthotropic curved plates (considering deflections due to shear) from which the displacements acting in the plate can be determined. The 11 equations consist of 5 equilibrium equations, 3 equations

relating resultant forces to strains, and 3 equations relating resultant moments with curvatures and twist.

The first five equations, expressing force equilibrium in the x - and y -directions, moment equilibrium about the x - and y -axes, and force equilibrium in the z -direction, are

$$\frac{\partial N_x}{\partial x} + \frac{\partial N_{xy}}{\partial y} = 0 \quad (1a)$$

$$\frac{\partial N_y}{\partial y} + \frac{\partial N_{xy}}{\partial x} = 0 \quad (1b)$$

$$Q_x - \frac{\partial M_x}{\partial x} + \frac{\partial M_{xy}}{\partial y} = 0 \quad (1c)$$

$$Q_y - \frac{\partial M_y}{\partial y} + \frac{\partial M_{xy}}{\partial x} = 0 \quad (1d)$$

$$\frac{\partial Q_x}{\partial x} + \frac{\partial Q_y}{\partial y} + N_x \frac{\partial^2 w}{\partial x^2} + N_y \left(\frac{1}{r} + \frac{\partial^2 w}{\partial y^2} \right) + 2N_{xy} \frac{\partial^2 w}{\partial x \partial y} + q = 0 \quad (1e)$$

It should be noted that in these equations, higher-order terms have been neglected in accordance with considerations similar to those of reference 6.

For the orthotropic curved plate, the relations between the resultant middle-surface forces and the middle-surface strains are (see appendix)

$$N_x = \frac{E_x}{1 - \mu'_x \mu'_y} \left[\frac{\partial u}{\partial x} + \mu'_y \left(\frac{\partial v}{\partial y} - \frac{w}{r} \right) \right] \quad (2a)$$

$$N_y = \frac{E_y}{1 - \mu'_x \mu'_y} \left(\frac{\partial v}{\partial y} - \frac{w}{r} + \mu'_x \frac{\partial u}{\partial x} \right) \quad (2b)$$

$$N_{xy} = G_{xy} \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \quad (2c)$$

From reference 3, the corresponding relations between resultant moments and curvatures and twist are

$$M_x = -\frac{D_x}{1 - \mu_x \mu_y} \left[\frac{\partial^2 w}{\partial x^2} - \frac{1}{D_{Q_x}} \frac{\partial Q_x}{\partial x} + \mu_y \left(\frac{\partial^2 w}{\partial y^2} - \frac{1}{D_{Q_y}} \frac{\partial Q_y}{\partial y} \right) \right] \quad (3a)$$

$$M_y = -\frac{D_y}{1 - \mu_x \mu_y} \left[\frac{\partial^2 w}{\partial y^2} - \frac{1}{D_{Q_y}} \frac{\partial Q_y}{\partial y} + \mu_x \left(\frac{\partial^2 w}{\partial x^2} - \frac{1}{D_{Q_x}} \frac{\partial Q_x}{\partial x} \right) \right] \quad (3b)$$

$$M_{xy} = \frac{1}{2} D_{xy} \left(2 \frac{\partial^2 w}{\partial x \partial y} - \frac{1}{D_{Q_y}} \frac{\partial Q_y}{\partial x} - \frac{1}{D_{Q_x}} \frac{\partial Q_x}{\partial y} \right) \quad (3c)$$

Equations (1), (2), and (3) are the 11 basic equations necessary for determining the forces, moments, and deflections acting in the plate. The number of equations can be reduced to five, however, by substituting equations (2) and (3) into equations (1). In this manner, five differential equations are obtained for determining the resultant transverse shear forces Q_x and Q_y and the displacements u , v , and w .

FIGURE 1.—Forces and moments acting on curved plate element.

The 11 basic equations presented are not restricted to deflection problems alone but may be applied to buckling problems as well by considering the changes that occur during buckling and modifying equations (1) accordingly. For equilibrium of the curved plate element after buckling, equations (1) can be written with N_x , N_{xy} , N_y , Q_x , Q_y , M_x , M_{xy} , M_y , and w replaced by $N_{x_0} + N_{x_1}$, $N_{xy_0} + N_{xy_1}$, $N_{y_0} + N_{y_1}$, $Q_{x_0} + Q_{x_1}$, $Q_{y_0} + Q_{y_1}$, $M_{x_0} + M_{x_1}$, $M_{xy_0} + M_{xy_1}$, $M_{y_0} + M_{y_1}$, and $w_0 + w_1$, respectively, where the subscript 0 refers to values prior to buckling and the subscript 1 refers to changes in these values that occur during buckling. For equilibrium of the curved plate element prior to buckling the following equations apply:

$$\frac{\partial N_{x_0}}{\partial x} + \frac{\partial N_{xy_0}}{\partial y} = 0$$

$$\frac{\partial N_{y_0}}{\partial y} + \frac{\partial N_{xy_0}}{\partial x} = 0$$

$$Q_{x_0} - \frac{\partial M_{x_0}}{\partial x} + \frac{\partial M_{xy_0}}{\partial y} = 0$$

$$Q_{y_0} - \frac{\partial M_{y_0}}{\partial y} + \frac{\partial M_{xy_0}}{\partial x} = 0$$

$$\frac{\partial Q_{x_0}}{\partial x} + \frac{\partial Q_{y_0}}{\partial y} + N_{x_0} \frac{\partial^2 w_0}{\partial x^2} + N_{y_0} \left(\frac{1}{r} + \frac{\partial^2 w_0}{\partial y^2} \right) + 2N_{xy_0} \frac{\partial^2 w_0}{\partial x \partial y} + q = 0$$

Subtracting the previous equations from equations (1) (as modified) gives the following equilibrium equations which apply to buckling problems:

$$\frac{\partial N_{x_1}}{\partial x} + \frac{\partial N_{xy_1}}{\partial y} = 0 \quad (4a)$$

$$\frac{\partial N_{y_1}}{\partial y} + \frac{\partial N_{xy_1}}{\partial x} = 0 \quad (4b)$$

$$Q_{x_1} - \frac{\partial M_{x_1}}{\partial x} + \frac{\partial M_{xy_1}}{\partial y} = 0 \quad (4c)$$

$$Q_{y_1} - \frac{\partial M_{y_1}}{\partial y} + \frac{\partial M_{xy_1}}{\partial x} = 0 \quad (4d)$$

$$\begin{aligned} & \frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{y_1}}{\partial y} + N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{x_1} \frac{\partial^2 (w_0 + w_1)}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + \\ & N_{y_1} \left[\frac{1}{r} + \frac{\partial^2 (w_0 + w_1)}{\partial y^2} \right] + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} + 2N_{xy_1} \frac{\partial^2 (w_0 + w_1)}{\partial x \partial y} = 0 \end{aligned} \quad (4e)$$

In equation (4e) the terms $N_{x_1} \frac{\partial^2 w_1}{\partial x^2}$, $N_{y_1} \frac{\partial^2 w_1}{\partial y^2}$, and $N_{xy_1} \frac{\partial^2 w_1}{\partial x \partial y}$ may be neglected since they will be small compared with $N_{x_0} \frac{\partial^2 w_1}{\partial x^2}$, $N_{y_0} \frac{\partial^2 w_1}{\partial y^2}$, and $N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y}$. Also, if the deflection

prior to buckling is zero or constant as occurs for many problems (for example, axial compression, hydrostatic pressure), all derivatives of w_0 vanish. For this type of problem equation (4e) becomes

$$\frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{y_1}}{\partial y} + N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + \frac{N_{y_1}}{r} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} = 0 \quad (4e')$$

The six equations relating changes in middle-surface resultant forces with buckling strains and changes in moment with buckling distortions are identical with equations (2) and (3) with the subscript 1 added to N_x , N_{xy} , N_y , Q_x , Q_y , M_x , M_{xy} , M_y , u , v , and w .

The 11 equations, given by equations (4) and equations (2) and (3) (with subscript 1), apply to buckling problems in general (with equation (4e) or (4e') as required) and can be used to obtain the critical values of the loads acting on the plate. As is shown in the next section, however, for the case in which the deflection prior to buckling is zero or constant, the 11 equations can be suitably combined to yield 3 equations in w_1 , Q_{x_1} , and Q_{y_1} , a form convenient for application to plates of sandwich construction.

Reduction to three equations for buckling problems in which the deflection prior to buckling is zero or constant.—The reduction of the 11 equations to 3 equations in w_1 , Q_{x_1} , and Q_{y_1} is achieved in several steps as follows:

By differentiating equation (4c) with respect to x , equation (4d) with respect to y , and adding the results to obtain the relationship

$$\frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{y_1}}{\partial y} = \frac{\partial^2 M_{x_1}}{\partial x^2} - 2 \frac{\partial^2 M_{xy_1}}{\partial x \partial y} + \frac{\partial^2 M_{y_1}}{\partial y^2}$$

equation (4e') may be rewritten as

$$\begin{aligned} & \frac{\partial^2 M_{x_1}}{\partial x^2} - 2 \frac{\partial^2 M_{xy_1}}{\partial x \partial y} + \frac{\partial^2 M_{y_1}}{\partial y^2} + \frac{N_{y_1}}{r} + N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + \\ & N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} = 0 \end{aligned} \quad (4e'')$$

Next, equations (2) and (3) (with subscript 1) are substituted into the equilibrium equations (4a) to (4d) and (4e'') to give

$$\frac{\partial^2 u_1}{\partial x^2} + \mu'_{xy} \frac{\partial^2 v_1}{\partial x \partial y} - \frac{\mu'_{xy}}{r} \frac{\partial w_1}{\partial x} + (1 - \mu'_{xy} \mu'_{yx}) \frac{G_{xy}}{E_x} \left(\frac{\partial^2 u_1}{\partial y^2} + \frac{\partial^2 v_1}{\partial x \partial y} \right) = 0 \quad (5)$$

$$\frac{\partial^2 v_1}{\partial y^2} - \frac{1}{r} \frac{\partial w_1}{\partial y} + \mu'_{yx} \frac{\partial^2 u_1}{\partial x \partial y} + (1 - \mu'_{xy} \mu'_{yx}) \frac{G_{xy}}{E_y} \left(\frac{\partial^2 v_1}{\partial x^2} + \frac{\partial^2 u_1}{\partial x \partial y} \right) = 0 \quad (6)$$

$$\begin{aligned} & Q_{x_1} + \frac{D_x}{1 - \mu_x \mu_y} \left(\frac{\partial^3 w_1}{\partial x^3} - \frac{1}{D_{q_x}} \frac{\partial^2 Q_{x_1}}{\partial x^2} + \mu_y \frac{\partial^3 w_1}{\partial x \partial y^2} - \frac{\mu_y}{D_{q_y}} \frac{\partial^2 Q_{y_1}}{\partial x \partial y} \right) + \\ & \frac{1}{2} D_{xy} \left(2 \frac{\partial^3 w_1}{\partial x \partial y^2} - \frac{1}{D_{q_x}} \frac{\partial^2 Q_{x_1}}{\partial y^2} - \frac{1}{D_{q_y}} \frac{\partial^2 Q_{y_1}}{\partial x \partial y} \right) = 0 \end{aligned} \quad (7)$$

$$Q_{v_1} + \frac{D_y}{1 - \mu_x \mu_y} \left(\frac{\partial^3 w_1}{\partial y^3} - \frac{1}{D_{Q_y}} \frac{\partial^2 Q_{v_1}}{\partial y^2} + \mu_x \frac{\partial^3 w_1}{\partial x^2 \partial y} - \frac{\mu_x}{D_{Q_x}} \frac{\partial^2 Q_{x_1}}{\partial x \partial y} \right) + \frac{1}{2} D_{xy} \left(2 \frac{\partial^3 w_1}{\partial x^2 \partial y} - \frac{1}{D_{Q_x}} \frac{\partial^2 Q_{x_1}}{\partial x \partial y} - \frac{1}{D_{Q_y}} \frac{\partial^2 Q_{v_1}}{\partial x^2} \right) = 0 \quad (8)$$

$$L_D w_1 - \frac{E_y}{r(1 - \mu'_x \mu'_y)} \left(\frac{\partial v_1}{\partial y} - \frac{w_1}{r} + \mu'_x \frac{\partial u_1}{\partial x} \right) - \left(N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right) - \frac{1}{D_{Q_x}} \left[\frac{D_x}{1 - \mu_x \mu_y} \frac{\partial^3 Q_{x_1}}{\partial x^3} + \left(\frac{\mu_x D_y}{1 - \mu_x \mu_y} + D_{xy} \right) \frac{\partial^3 Q_{x_1}}{\partial x \partial y^2} \right] - \frac{1}{D_{Q_y}} \left[\frac{D_y}{1 - \mu_x \mu_y} \frac{\partial^3 Q_{v_1}}{\partial y^3} + \left(\frac{\mu_y D_x}{1 - \mu_x \mu_y} + D_{xy} \right) \frac{\partial^3 Q_{v_1}}{\partial x^2 \partial y} \right] = 0 \quad (9)$$

where L_D is the linear differential operator defined by

$$L_D = \frac{D_x}{1 - \mu_x \mu_y} \frac{\partial^4}{\partial x^4} + \left(\frac{\mu_y D_x}{1 - \mu_x \mu_y} + 2D_{xy} + \frac{\mu_x D_y}{1 - \mu_x \mu_y} \right) \frac{\partial^4}{\partial x^2 \partial y^2} + \frac{D_y}{1 - \mu_x \mu_y} \frac{\partial^4}{\partial y^4}$$

At this point, six equations have been eliminated and, therefore, five equations remain—equations (5), (6), (7), (8), and (9) in u_1 , v_1 , w_1 , Q_{x_1} , and Q_{v_1} .

A further reduction in the number of equations and unknowns is effected by first solving equations (5) and (6) to obtain relations from which u_1 and v_1 can be determined and then substituting for u_1 and v_1 in equation (9). The expressions obtained by solving equations (5) and (6), in accordance with the rules governing the multiplication of linear operators, are

$$r L_E u_1 = \mu'_y \frac{G_{xy}}{E_y} \frac{\partial^3 w_1}{\partial x^3} - \frac{G_{xy}}{E_x} \frac{\partial^3 w_1}{\partial x \partial y^2} \quad (10)$$

and

$$r L_E v_1 = \left(1 - \mu'_y \frac{G_{xy}}{E_y} \right) \frac{\partial^3 w_1}{\partial x^2 \partial y} + \frac{G_{xy}}{E_x} \frac{\partial^3 w_1}{\partial y^3} \quad (11)$$

where L_E is the linear differential operator defined by

$$L_E = \frac{G_{xy}}{E_y} \frac{\partial^4}{\partial x^4} + \left(1 - \mu'_x \frac{G_{xy}}{E_x} - \mu'_y \frac{G_{xy}}{E_y} \right) \frac{\partial^4}{\partial x^2 \partial y^2} + \frac{G_{xy}}{E_x} \frac{\partial^4}{\partial y^4}$$

The relationships given by equations (10) and (11) may be written in a form more suitable for substitution into equation (9) by differentiating equation (10) with respect to x , equation (11) with respect to y , and then, symbolically solving the equations for $\frac{\partial u_1}{\partial x}$ and $\frac{\partial v_1}{\partial y}$, respectively, to give

$$\frac{\partial u_1}{\partial x} = L_E^{-1} \left(\frac{\mu'_y}{r} \frac{G_{xy}}{E_y} \frac{\partial^4 w_1}{\partial x^4} - \frac{G_{xy}}{r E_x} \frac{\partial^4 w_1}{\partial x^2 \partial y^2} \right) \quad (12)$$

$$\frac{\partial v_1}{\partial y} = L_E^{-1} \left(\frac{1 - \mu'_y \frac{G_{xy}}{E_y}}{r} \frac{\partial^4 w_1}{\partial x^2 \partial y^2} + \frac{G_{xy}}{r E_x} \frac{\partial^4 w_1}{\partial y^4} \right) \quad (13)$$

where L_E^{-1} is defined by $L_E^{-1}(L_E w_1) = L_E(L_E^{-1} w_1) = w_1$. The inverse operator L_E^{-1} is similar to the inverse operator ∇^{-4}

defined in reference 7, and, as is shown subsequently, L_E^{-1} reduces to ∇^{-4} for the special case of the isotropic plate.

Substituting the expressions for $\frac{\partial u_1}{\partial x}$ and $\frac{\partial v_1}{\partial y}$ from equations

(12) and (13) into equation (9) and replacing $\frac{w_1}{r}$ by

$L_E^{-1} \left(L_E \frac{w_1}{r} \right)$ results in the following equation:

$$L_D w_1 + \frac{G_{xy}}{r^2} L_E^{-1} \frac{\partial^4 w_1}{\partial x^4} - \left(N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right) - \frac{1}{D_{Q_x}} \left[\frac{D_x}{1 - \mu_x \mu_y} \frac{\partial^3 Q_{x_1}}{\partial x^3} + \left(\frac{\mu_x D_y}{1 - \mu_x \mu_y} + D_{xy} \right) \frac{\partial^3 Q_{x_1}}{\partial x \partial y^2} \right] - \frac{1}{D_{Q_y}} \left[\frac{D_y}{1 - \mu_x \mu_y} \frac{\partial^3 Q_{v_1}}{\partial y^3} + \left(\frac{\mu_y D_x}{1 - \mu_x \mu_y} + D_{xy} \right) \frac{\partial^3 Q_{v_1}}{\partial x^2 \partial y} \right] = 0 \quad (14)$$

At this stage, the original 11 equations have been reduced to the 3 equations (14), (7), and (8), in the 3 unknowns w_1 , Q_{x_1} , and Q_{v_1} .

For most problems, equations (14), (7), and (8), together with proper boundary conditions, can determine the elastic stability criteria for an orthotropic curved plate subjected to middle-surface loadings. It should be noted, however, that the three equations are not sufficient if boundary conditions are specified on the displacements u_1 and v_1 . For boundary conditions on u_1 and v_1 , as well as w_1 , equations (10) and (11) must also be employed. When boundary conditions are not specified on u_1 and v_1 (the case when only equations (14), (7), and (8) are used), certain boundary conditions are implied, nevertheless, by equations (10) and (11), consistent with the expression for w_1 . A discussion of similar implied boundary conditions on u_1 and v_1 is included in reference 7.

SPECIAL CASES OF BUCKLING EQUATIONS

Isotropic curved sandwich plate with non-direct-stress-carrying core.—For the isotropic sandwich plate with non-direct-stress-carrying core, the physical constants bear the following relationships to those of the orthotropic plate:

$$D_{Q_x} = D_{Q_y} = D_Q$$

$$\mu_x = \mu_y = \mu'_x = \mu'_y = \mu$$

$$D_x = D_y = D_s(1 - \mu^2)$$

$$D_{xy} = D_s(1 - \mu)$$

$$E_x = E_y = 2E_s t_s$$

$$G_{xy} = \frac{E_s t_s}{1 + \mu}$$

These relationships permit equation (14) to be simplified as follows:

$$D_s \nabla^4 w_1 + \frac{2t_s E_s}{r^2} \nabla^{-4} \frac{\partial^4 w_1}{\partial x^4} - \left(N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right) - \frac{D_s}{D_Q} \nabla^2 \left(\frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{v_1}}{\partial y} \right) = 0 \quad (15)$$

where

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$$

$$\nabla^4 = \frac{\partial^4}{\partial x^4} + 2 \frac{\partial^4}{\partial x^2 \partial y^2} + \frac{\partial^4}{\partial y^4}$$

and ∇^{-4} is defined by $\nabla^{-4}(\nabla^4 w_1) = \nabla^4(\nabla^{-4} w_1) = w_1$.

In this case, however, equations (7) and (8) are not needed to obtain the quantity $\frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{y_1}}{\partial y}$, since this quantity can be found more conveniently from equation (4e'). From equation (4e'), therefore,

$$\frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{y_1}}{\partial y} = - \left(\frac{N_{v_1}}{r} + N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right)$$

Substituting for $\frac{\partial Q_{x_1}}{\partial x} + \frac{\partial Q_{y_1}}{\partial y}$ in equation (15) gives

$$D_s \Delta^4 w_1 + \frac{2t_s E_s}{r^2} \nabla^{-4} \frac{\partial^4 w_1}{\partial x^4} - \frac{D_s}{D_q} \nabla^2 \left(- \frac{N_{v_1}}{r} \right) - \left(1 - \frac{D_s}{D_q} \nabla^2 \right) \left(N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right) = 0 \quad (16)$$

The term $-N_{v_1}/r$, which appears in equation (14) for the orthotropic plate as $\frac{G_{xy}}{r^2} L_E^{-1} \frac{\partial^4 w_1}{\partial x^4}$, reduces to $\frac{2t_s E_s}{r^2} \nabla^{-4} \frac{\partial^4 w_1}{\partial x^4}$ for the case of the isotropic plate. If this result is used in equation (16), the equation of equilibrium for the isotropic curved sandwich plate with non-direct-stress-carrying core becomes

$$D_s \nabla^4 w_1 + \left(1 - \frac{D_s}{D_q} \nabla^2 \right) \left[\frac{2t_s E_s}{r^2} \nabla^{-4} \frac{\partial^4 w_1}{\partial x^4} - \left(N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right) \right] = 0 \quad (17)$$

If the radius is taken infinite, equation (17) becomes equivalent to equation (71) of reference 4.

Isotropic curved plate, deflections due to shear neglected.—The present theory can be reduced to a known theory for ordinary curved plates by appropriate substitutions for the physical constants. For an ordinary plate, the physical constants become

$$D_{Q_x} = D_{Q_y} = \infty \quad (\text{no shear deflections})$$

$$\mu_x = \mu_y = \mu'_x = \mu'_y = \mu$$

$$D_x = D_y = D(1 - \mu^2)$$

$$D_{xy} = D(1 - \mu)$$

$$E_x = E_y = Et$$

$$G_{xy} = \frac{Et}{2(1 + \mu)}$$

Upon substitution of these constants into equation (14), the resulting equation becomes independent of equations (7) and (8) and the equilibrium equation of the ordinary curved plate, therefore, is given by

$$D \nabla^4 w_1 + \frac{Et}{r^2} \nabla^{-4} \frac{\partial^4 w_1}{\partial x^4} - \left(N_{x_0} \frac{\partial^2 w_1}{\partial x^2} + N_{y_0} \frac{\partial^2 w_1}{\partial y^2} + 2N_{xy_0} \frac{\partial^2 w_1}{\partial x \partial y} \right) = 0 \quad (18)$$

Equation (18) is equivalent to the modified equilibrium equation for ordinary curved plates presented in reference 7.

CONCLUDING REMARKS

A theory has been developed for analyzing the elastic behavior of orthotropic curved plates, that takes into account the effect of deflections due to shear and requires the use of 12 physical constants to characterize the plate. Seven of the physical constants appearing in the equations of equilibrium are directly associated with the flat-orthotropic-plate theory presented in NACA Rep. 899. The remaining five physical constants are included in the present theory to account for the stretching under loading of the middle surface of the curved plate.

For each type of orthotropic plate, the 12 physical constants may be evaluated either from the geometry of the cross sections and the properties of the materials used or by direct tests conducted on sample specimens. Because two reciprocal relationships exist (see appendix), only 10 of the constants need be determined independently.

The theory presented in this report does not take into account the compressibility of the sandwich plate in a direction normal to the faces. Such an effect does not enter into flat-sandwich-plate theory but might be of importance in certain types of curved sandwich plates where the elastic constants of the core material are small compared with those of the face material.

For practical sandwiches of the end-grain-balsa or corrugated-core types, order-of-magnitude considerations lead to the conclusion that the effect of core compressibility will be negligible as regards both buckling loads and deflections. For sandwiches with less stiff cores—for example, cellular cellulose acetate—the effect of core compressibility will be more important. Even for such cores, however, in the case of all the numerical examples given in NACA TN 1832, the effect of core compressibility is negligible in comparison with the effect of transverse shear deformations for sandwich-type circular cylindrical shells. The present theory, in which the core is assumed to be incompressible in a direction normal to the faces, appears, therefore, to be applicable to most practical sandwich plates.

APPENDIX

DERIVATION OF MIDDLE-SURFACE FORCE-DISTORTION RELATIONSHIPS

The orthotropic curved plate (effects of transverse shear being considered) is characterized by 12 physical constants, 7 of which are associated with flat plates, as presented in reference 3. The remaining five constants enter the present theory because of the additional stretching strain developed under loading in the middle surface of the curved plate. In this appendix the five additional constants are defined, and expressions for the resultant forces, involving these constants, are derived.

Physical constants.—The seven flat-plate constants are the flexural stiffnesses D_x and D_y , the flexural Poisson ratios μ_x and μ_y , the twisting stiffness D_{xy} , and the transverse shear stiffnesses D_{Q_x} and D_{Q_y} . As derived in reference 3, the first four of these constants are related by

$$\mu_x D_y = \mu_y D_x$$

The five additional constants appearing in the curved-plate theory are the extensional stiffnesses E_x and E_y , the extensional Poisson ratios μ'_x and μ'_y , and the shearing stiffness G_{xy} . The first four constants are found by a procedure similar to that used in reference 3 to be related by

$$\mu'_x E_y = \mu'_y E_x$$

As a result of these two reciprocal relationships, only 10 of the 12 physical constants need be determined independently.

The five additional physical constants are defined in the same manner as the flat-plate constants of reference 3—that is, by considering the effect of imposing particular loading conditions on the element shown in figure 1. To obtain E_x , for example, only the middle-surface forces N_x are assumed to be acting on the element. As a result of this loading, the strain ϵ_x is induced in the middle surface.

The stiffness E_x is then defined by the relation $E_x = \frac{N_x}{\epsilon_x}$ when only N_x is acting.

The Poisson effect of the forces N_x acting on the element is to introduce a strain ϵ_y , negative with respect to ϵ_x , in the middle surface. The constant μ'_x is then defined by the relation $\mu'_x = -\frac{\epsilon_y}{\epsilon_x}$ when only N_x is acting.

In a similar manner, E_y , μ'_y , and G_{xy} are defined as $E_y = \frac{N_y}{\epsilon_y}$ when only N_y is acting, $\mu'_y = -\frac{\epsilon_x}{\epsilon_y}$ when only N_y is acting, and $G_{xy} = \frac{N_{xy}}{\gamma_{xy}}$.

Resultant forces.—The relations between the elastic middle-surface strains and forces, satisfying the foregoing definitions, can be written as

$$\left. \begin{aligned} \epsilon_x &= \frac{N_x}{E_x} - \mu'_y \frac{N_y}{E_y} \\ \epsilon_y &= \frac{N_y}{E_y} - \mu'_x \frac{N_x}{E_x} \\ \gamma_{xy} &= \frac{N_{xy}}{G_{xy}} \end{aligned} \right\} \quad (A1)$$

The three strain equations can be solved for N_x , N_y , and N_{xy} in terms of the strains to give

$$\left. \begin{aligned} N_x &= \frac{E_x}{1 - \mu'_x \mu'_y} (\epsilon_x + \mu'_y \epsilon_y) \\ N_y &= \frac{E_y}{1 - \mu'_x \mu'_y} (\epsilon_y + \mu'_x \epsilon_x) \\ N_{xy} &= G_{xy} \gamma_{xy} \end{aligned} \right\} \quad (A2)$$

Substituting the expressions for the middle-surface strains of a cylindrical section in terms of middle-surface displacements

$$\begin{aligned} \epsilon_x &= \frac{\partial u}{\partial x} \\ \epsilon_y &= \frac{\partial v}{\partial y} - \frac{w}{r} \\ \gamma_{xy} &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \end{aligned}$$

into equation (A2) gives

$$\left. \begin{aligned} N_x &= \frac{E_x}{1 - \mu'_x \mu'_y} \left[\frac{\partial u}{\partial x} + \mu'_y \left(\frac{\partial v}{\partial y} - \frac{w}{r} \right) \right] \\ N_y &= \frac{E_y}{1 - \mu'_x \mu'_y} \left(\frac{\partial v}{\partial y} - \frac{w}{r} + \mu'_x \frac{\partial u}{\partial x} \right) \\ N_{xy} &= G_{xy} \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \end{aligned} \right\} \quad (A3)$$

These equations are used in the derivation of the equilibrium equations.

REPORT 1009

INVESTIGATION OF FRETTING BY MICROSCOPIC OBSERVATION¹

By DOUGLAS GODFREY

SUMMARY

An experimental investigation, using microscopic observation and color motion photomicrographs of the action, was conducted to determine the cause of fretting. Glass and other noncorrosive materials, as well as metals, were used as specimens. A very simple apparatus vibrated convex surfaces in contact with stationary flat surfaces at frequencies of 120 cycles or less than 1 cycle per second, an amplitude of 0.001 inch, and a load of 0.2 pound.

The observations and analysis led to the conclusions that fretting was initiated by the loosening, due to inherent adhesive forces, of finely divided and apparently virgin material, and that its initiation is independent of vibratory motion or high sliding speeds. The fretting of platinum, glass, quartz, ruby, and mica relegated the role of oxidation as a cause to that of a secondary factor. Fretting occurred to clean nonmetals and metals readily, and glass microscope slides and steel balls provided an excellent method for visual studies.

INTRODUCTION

Fretting, defined as surface failure that may occur when closely fitting metal surfaces experience slight relative motion, damages many machine parts subject to vibration. The phenomenon of fretting (also known as fretting corrosion and friction oxidation) is principally characterized by surface stain, pitting, and the generation of oxides, as described in detail in references 1 and 2. The determination of the cause of fretting has been the object of several research programs. The research reported in reference 2 supports Tomlinson's theory of molecular attrition (reference 3) that proposes that the cause of fretting is a physical action, or specifically that the disintegration of the metal surface is due to "molecular plucking." More recently, chemical action has been reported to be of primary importance

(reference 4). Other investigators (for example, references 5 and 6) have advanced electrolytic, abrasion, welding, fatigue, and "vibrational decay" theories to explain the action that produces fretting. These theories are incompatible or divergent and more experimental evidence is needed before any one of them may be generally accepted.

The failure of certain aircraft parts due to fretting has produced a new incentive toward solving the problem of the prevention of the phenomenon. Antifriction bearings subject to rotational oscillation and side-thrust vibration experience the greatest amount of fretting, and such parts as connecting rods, knuckle pins, splined shafts, and clamped and bolted flanges suffer deleterious effects (reference 1).

The research reported herein was conducted at the NACA Lewis laboratory during 1949 to observe and to analyze the action of fretting in its initial stages in order to determine its cause. Inasmuch as the limits of mechanical variables such as load, frequency, and amplitude have been established (reference 2), this investigation was limited to microscopic observation, debris analysis, and surface analysis of fretting areas. The nonmetallic and noncorrosive materials, glass, quartz, ruby, and mica, and the metal platinum were used as specimens because their fretting would indicate whether the primary action was physical or chemical; in addition, the nonmetallic materials eliminated the possibility of ordinary welding, simplified the debris analysis, and in some cases permitted microscopic observation or color motion photomicrographs of the action (reference 7). The color motion photomicrographs describe fretting more effectively than words or black-and-white photomicrographs.

Fretting was induced by a very simple apparatus, which vibrated a convex (usually spherical) surface in contact with a flat surface at frequencies of 120 cycles or less than 1 cycle per second, an amplitude of 0.001 inch, and a load of 0.2 pound.

FIGURE 1.—Fretting apparatus.

FIGURE 2.—Photomicrograph with vertical illumination and red filter of chrome-alloy steel ball through glass slide showing interference bands surrounding contact area. $\times 100$.

APPARATUS, MATERIALS, AND PROCEDURE

A photograph of the apparatus is shown in figure 1. The vibrating action of 120 cycles per second with an amplitude of 0.001 inch was induced by a solenoid. The specimen with the convex surface was firmly attached to the plunger of the solenoid, which was horizontal. The specimen with the flat surface was held stationary at one end and loaded vertically by a flat spring. The spring caused the flat surface to exert a load of approximately 0.2 pound on the convex surface.

The apparatus could be attached to the mechanical stage of a microscope, which permitted microscopic observation of the contact area with vertical or oblique illumination. With transparent flat specimens, the contact area could readily be located because it was surrounded by concentric interference bands (fig. 2). Amplitude was measured by noting the distance between the extreme positions of a scratch mark on the vibrating surface. The experiments conducted at 120 cycles per second were divided into three groups: (1) the preliminary metal against metal, (2) the metal against nonmetal, and (3) the nonmetal against nonmetal. No general material survey was made and the number of metals used was limited.

In the metal-against-metal group, mild steel, chrome steel, stainless steel, copper, and aluminum were vibrated against mild steel essentially to ascertain whether the apparatus would induce fretting with satisfactory reproducibility. In the metal-against-nonmetal group, the five metals plus platinum were each vibrated against glass microscope slides, mica, and Lucite and extensive observations were made with $\frac{1}{2}$ -inch-diameter chrome-alloy steel (SAE 52100) balls and the glass slides. Glass was used as one of the sur-

faces because it is rigid, noncorrosive, and transparent. These properties were desirable to permit observation of the action as well as to simplify debris analysis. The statement is made in reference 2 that glass not only produces fretting on steel but is itself attacked; the ability of glass to pick up metal during sliding is demonstrated in reference 8. In the third group, glass, quartz, ruby, mica, and Lucite were vibrated against one another. All the materials were shaped into convex or flat pieces as required and finished to a surface roughness of 1 to 3 root mean square by fine grinding and polishing.

A group of experiments that are considered to be $\frac{1}{2}$ -cycle experiments were conducted with an adapter on the apparatus, which provided for sliding the glass microscope slide over the surface of the stationary ball at a speed of approximately 0.002 inch per second or less. The motion was caused by hand-turning a fine screw to which the glass was attached. The direction was reversed each 0.001 inch, and the frequency was considered 1 cycle per second or less. A slow-motion vibration was thus simulated and the action that occurs in $\frac{1}{2}$ cycle was observed.

All specimens were thoroughly cleaned immediately before being mounted in the apparatus. The metal cleaning consisted in degreasing in an organic solvent followed by scrubbing with surgical cotton in a paste of levigated alumina, a thorough rinse in tap water, a rinse in 95-percent alcohol, and drying in air. Particular effort was made to wash off all adhering alumina. The glass, ruby, quartz, and mica specimens were cleaned in fresh sodium dichromate-sulfuric acid cleaning solution followed by rinse in tap water and distilled water and oven drying. The Lucite was wiped clean with lens tissue.

The number of cycles that any pair of specimens had experienced was determined by measuring the length of time current was supplied to the solenoid. In those cases in which the flat specimens were not transparent, the vibration was induced for periods of 1, 2, 4, 8, 16, 32, 60, 120, 180, 300, and 600 seconds cumulatively. After each period, the flat specimen was removed and the spots on the convex specimen and on the flat specimen were each microscopically examined. Photomicrographs were taken in some cases to aid in the description of the action. When transparent specimens were used, the complete action could be viewed or photographed with ease. The vibration could be stopped at any time, however, and the contact area viewed or photographed at rest.

RESULTS AND DISCUSSION

PRELIMINARY METAL AGAINST METAL

In the preliminary metal-against-metal experiments, each of the several pairs of specimens investigated exhibited fretting within approximately 300 seconds and produced the characteristic debris and wear area. The pattern of the spot on the flat surface was always similar to the pattern of the spot on the convex surface. These experiments revealed that load, amplitude, and frequency were such

as to produce fretting quickly and that the amount of debris and the size of the wear spot could be reproduced for any given pair in the same number of cycles.

The introduction of a mineral oil film increased the time required to produce fretting but did not otherwise appreciably alter the results.

METAL AGAINST NONMETAL

Photomicrographs of the contact area at various stages of the fretting caused by vibrating a chrome-alloy steel ball against a glass specimen are shown in figure 3. Within $\frac{1}{4}$ second (30 cycles), fretting was evident as a small black irregular spot on the ball, which steadily grew in size and became discontinuous (figs. 3 (a) and 3 (b)). A brown, sticky semifluid oxide was then generated within the contact area, spread over the glass, and adhered tenaciously to it. This oxide shares the contact area with the black material (figs. 3 (b) to 3 (f)). A rust-colored fine dry oxide was also formed that was extruded from the area in increasing quantities and accumulated just outside the rubbing area, as evident in figures 3 (b) to 3 (f). Active black spots shifted position as the phenomenon progressed because of disintegration of peaks bearing the load for the moment. Color motion photomicrographs of this action can be seen in the aforementioned film.

After approximately 40,000 cycles, the action stabilized to

a steady-growth condition with continued generation of material in the black spots surrounded by brown semifluid oxide and the formation of fine powder-like oxide. The black color of the active areas indicated the presence of finely divided iron; this indication was further confirmed by subsequent change to dark brown and then to rust brown. If the vibration was stopped, the trapped black material could be seen to gradually turn brown. Finely divided iron, ferrous oxide FeO , and ferrosferic oxide Fe_3O_4 are black, whereas ferric oxide Fe_2O_3 and its hydrated form $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ are reddish. The fretting debris of steel was identified by electron diffraction as Fe_2O_3 and the color changes that occurred suggest the progressive oxidation of the iron. Fretting is apparently initiated by the loosening, due to inherent adhesive forces, of extremely finely divided and apparently virgin material that is extruded and reacts with oxygen simultaneously. Examination of the ball after the experiment revealed a flat oxide-encrusted spot (fig. 4 (a)), which on subsequent cleaning was revealed to be an abraded flat spot (fig. 4 (b)). The sticky oxide on the glass was removed with difficulty but completely with acids, and a striated cracked area was revealed. The striations could not be brought into sharp focus with the microscope, indicating appreciable depth and irregularity (fig. 5 (a)). If the action was continued for longer periods, the glass fragmented locally (fig. 5 (b)) and was pitted.

The introduction of a film of pure mineral oil between the surfaces increased the time for the first evidence of fretting

action 50 times. This delay also provided a slow-motion study of the fretting process and showed that oxides were produced in the same manner in the presence of oil. Once the phenomena were well under way, the modifying effect of the oil was reduced.

Results obtained when other metals were vibrated against glass slides supported the explanation of fretting deduced from the steel-glass experiments. In one experiment, flame-cleaned platinum foil supported by a steel ball was vibrated in contact with clean glass. The generation of a black powder in the characteristic way was observed (fig. 6). This powder remained black and that which adhered to the glass could be completely removed only by a 4-hour treatment in aqua regia. Color, acid resistance, electron-diffraction patterns, and source indicated that the material was finely divided platinum (platinum black). Because platinum will not oxidize in air at any temperature, the theory that oxidation is a primary cause of fretting is not supported.

The action of a stainless-steel (SAE 30705) convex surface against the flat glass was similar to that of the chrome-alloy steel balls except that the number and the extent of the active black areas were greater. Copper produced a brownish-black material that also adhered tenaciously to the glass. At times, large particles of metallic copper could be seen to leave the contact area. During the third minute of vibration, the contact area assumed the greenish tint characteristic of copper oxide. Both these metals were pitted and abraded and the glass was striated.

Under the conditions of the $\frac{1}{2}$ -cycle experiment, two types of action were observed. If the surface of the ball was previously roughened with 2/0 emery paper, the glass would polish the contact area on the ball and become smeared with the semifluid oxide, which would again tenaciously adhere to the glass. The amount of debris accumulated in three $\frac{1}{2}$ cycles of vibration is shown in figure 7 (a).

An increase in frictional force was apparent when the oxide was present between the surfaces. This greater motivating force was required to continue relative sliding because a non-lubricating material was present between the surfaces and tenaciously adhered to each. The oxide itself was sheared and the two new faces thus formed became the sliding surfaces. If a ball with its original polished surface was used, much less oxide would be smeared, but the movement would cause the glass to grip the ball and as the relative sliding continued the glass would visibly and audibly crack. The cracking occurred at the trailing edge of the contact area. A photomicrograph of the glass in the process of forming a second crack is shown in figure 7 (b). The row of cracks produced in the glass during continued sliding is shown in figure 7 (c). The smearing of the metallic oxide onto the glass and the cracking of the glass are apparently due to a great amount of adhesion permitted by the extreme cleanliness of the specimens. The surface finish on the ball determines which phenomenon will occur. A rough surface supports the load on a number of peaks, the average particle of which is relatively exposed. Sliding of the smooth glass over these peaks results in disintegration of the peaks and subsequent oxidation of the removed metal. A smooth polished surface on the ball supports the load on a few broad undulations, the material of which is secure. Sliding of the smooth glass over these contact areas results in failure of the glass rather than the metal. This concept is in agreement with reference 8, which presents data to show that the amount of

material transferred from base to rider increased with increase in surface roughness if the rider was harder than the base. With the steel ball considered as the rider and the steel harder than the glass, some incongruity may exist in this comparison in that the glass picked up material from the steel.

The glass appeared to plow into the aluminum, scoring it heavily. Large metallic pieces were mixed with a grayish-black powder. Some of the debris adhered tenaciously to the glass in the characteristic manner. The powder was insoluble in nitric acid but soluble in alkali, indicating that aluminum was still present. Mica and Lucite always wore away the metal surfaces and produced very great amounts of flocculent debris. Observation of the action of the metals was difficult because of the great dilution of the metal debris by the voluminous debris from the flat specimen. This experiment indicated that no property peculiar to glass was inducing the action.

NONMETALS AGAINST NONMETALS

The independence of fretting from chemical action was indicated in a group of experiments involving the nonmetallic, nonoxidizing materials with glass vibrated against quartz, ruby, or mica. By vibrating a ruby with a convex surface against a glass slide and observing the action under a microscope, surface disintegration could be seen to occur. The glass, after 2 to 3 seconds of rubbing, suddenly collapsed locally and distributed debris about the contact area, leaving a pit. This action shifted the bearing area to the edge of the pit and the disintegration was continued (fig. 8). An early stage of disintegration with two pits formed is shown in figure 8 (a), whereas the advanced stage of 20 or more pits is shown in figure 8 (b). The ruby was simply further polished, that is, the microscopic scratches were erased. Quartz against glass acted the same as ruby against glass. Mica

FIGURE 8.—Photomicrographs showing results of fretting between ruby and glass. $\times 120$.

against a glass ball and Lucite against a glass ball also behaved similarly. In all cases, the debris was produced, extruded, and accumulated in the same physical manner observed with metal debris, except that no change in color took place. Fretting occurred to mica in the least number of cycles, the number required being progressively greater for Lucite, glass, quartz, and ruby, which is also the order of increasing hardness of the materials. The tendency for fretting between the various nonmetals and glass and the amount of debris generated therefore appear to be inversely proportional to the hardness of the nonmetal.

CONCLUDING REMARKS

The observations made indicate that fretting can occur between two nonmetals. The susceptibility to fretting of nonoxidizing materials such as glass, quartz, ruby, mica, and platinum relegates the role of oxidation as a cause to that of a secondary factor and indicates that finely divided and apparently virgin material is first produced. In the metals, this production of virgin metal is suggested by the color changes through which the metal passed as it oxidized. The oxides are therefore considered a byproduct of the initial action. The spontaneity of the oxidation is probably due to the increased chemical activity of the particles. This increase is called mechanical activation in reference 9, which also states that the increase is more than that produced by cleanliness or reduced particle size. The oxide formation was induced at extremely low speeds and light loads where the dissipation of frictional heat is sufficiently rapid to minimize the occurrence of local hot spots. The possibility of fretting being caused by rubbing off a regenerative high-temperature-forming oxide film is therefore unlikely.

The conclusion is made in reference 2 that alternating slip is a necessary condition for fretting. The production of a smear on the glass surface in $\frac{1}{2}$ cycle and the cracking of glass on smooth metal indicate that alternation of motion is unnecessary to initiate fretting, although alternation does give it its usual characteristics. This idea is supported by the

observation that fretting starts with the sliding or slip. Lowering the frequency only decreases the rate at which fretting occurs. This relation indicates that the basic cause of fretting is independent of frequency.

The metal transfer caused by sliding one metal over another demonstrated in references 8 and 10 was attributed to adhesion. Similarly, in the experiments reported herein the action observed, namely, removal of material, cracking, and general surface destruction, was attributed to adhesion, which leads to the conclusion that fretting is a manifestation of the adhesion component of friction.

RESULTS AND CONCLUSIONS

An experimental investigation was conducted to determine the cause of fretting. Glass and other noncorrosive materials were vibrated in contact with one another and with metals and microscopic observation was made of the action. Convex surfaces were vibrated in contact with stationary flat surfaces at frequencies of 120 cycles or less than 1 cycle per second, an amplitude of 0.001 inch, and a load of 0.2 pound.

The following results and conclusions were indicated:

1. Fretting is initiated by the loosening, due to inherent adhesive forces, of extremely finely divided and apparently virgin material that is extruded from the contact area and reacts with oxygen simultaneously.
2. The fretting of platinum, glass, quartz, ruby, and mica relegated the role of oxidation as a cause to that of a secondary factor.
3. Fretting readily occurred between clean nonmetals and metals. Steel balls vibrating in contact with glass microscope slides provided an excellent method for observing fretting.
4. The initiating of fretting is independent of vibratory motion or high sliding speeds.

REPORT 1010

A RECURRENCE MATRIX SOLUTION FOR THE DYNAMIC RESPONSE OF AIRCRAFT IN GUSTS¹

By JOHN C. HOUBOLT

SUMMARY

A systematic procedure is developed for the calculation of the structural response of aircraft flying through a gust by use of difference equations and matrix notation. The use of difference equations in the solution of dynamic problems is first illustrated by means of a simple-damped-oscillator example. A detailed analysis is then given which leads to a recurrence matrix equation for the determination of the response of an airplane in a gust. The method takes into account wing bending and twisting deformations, fuselage deflection, vertical and pitching motion of the airplane, and some tail forces. The method is based on aerodynamic strip theory, but compressibility and three-dimensional aerodynamic effects can be taken into account approximately by means of over-all corrections. Either a sharp-edge gust or a gust of arbitrary shape in the spanwise or flight directions may be treated. In order to aid in the application of the method to any specific case, a suggested computational procedure is included.

The possibilities of applying the method to a variety of transient aircraft problems, such as landing, are brought out. A brief review of matrix algebra, covering the extent to which it is used in the analysis, is also included.

INTRODUCTION

In the problem of an airplane flying through gusts, accurate predictions of stresses are not always obtained if the interaction between aerodynamic loads and structural deformations is not considered. The present report gives a method for determining the dynamic response of aircraft in gusts in which this interaction is considered. An approach is employed which is a departure from the usual modal type of solution. The time derivatives in the integrodifferential equations of motion of the airplane are replaced by appropriate difference expressions and use is made of matrix notation to express conveniently the conditions of equilibrium at a number of points along the wing span. The result is a systematic procedure which is complete and general in form. The airplane is assumed to be free to translate and pitch. Wing bending, wing twist, and fuselage flexibility are all included. Tail forces due to vertical motion, angle of attack, and gust penetration are also included in the analysis.

With the method, a gust with any gradient in the direction of flight or along the span may be treated. The method is

based on aerodynamic strip theory, but over-all compressibility and aspect-ratio corrections may be included without difficulty, if desired. One such over-all correction is indicated.

In the first part of the report the method of using difference equations in the solution of dynamic problems is illustrated by an example in which the transient response of a simple oscillator is determined. The analysis for the determination of the response of an airplane in a gust is then given. In the following section a computational procedure is suggested. This section is not intended to describe or add to the understanding of the analysis, but by following the directions indicated, the response of any airplane may be found without following through the complete details of the analysis.

Supplementary definitions and derivations are presented in appendixes. Appendix A summarizes the various matrix coefficients and matrices that are used in the analysis, appendix B gives a derivation of the difference equations, appendix C gives a derivation of the flexibility matrices, appendix D gives a derivation of a recurrence equation for evaluating the form of Duhamel's integral which involves an exponential kernel, and appendix E presents a review of the fundamentals of matrix algebra. It is suggested that those not familiar with matrix algebra read appendix E before reading the analysis.

SYMBOLS

a	distance between leading edge of wing and elastic axis
a_1	coefficient used in unsteady lift function for sudden change in angle of attack
A	aspect ratio of wing
A_t	aspect ratio of horizontal tail
b	semispan of wing
c	chord of wing
c_o	chord at wing midspan
c_{o_t}	midspan chord of tail
c_t	mean aerodynamic chord of tail
e	distance between mass center of wing cross section and elastic axis of wing, positive when elastic axis lies forward of mass center
E	Young's modulus of elasticity

¹ Supersedes NACA TN 2060, "A Recurrence Matrix Solution for the Dynamic Response of Aircraft in Gusts" by John C. Houbolt, 1950.

F	suddenly applied force	w	deflection of elastic axis of wing, positive upward, or deflection of mass oscillator
G	shear modulus of elasticity	w_f	deflection of fuselage, positive upward
i	integers 0, 1, 2, 3, 4, and 5 used to designate stations (for most part used as parenthetical numbers, that is, $w(3)$ is deflection at station 3)	W_1	fuselage modal function, zero at wing elastic axis and unity at tail one-quarter-chord location
I	bending moment of inertia	x	distance along fuselage measured from wing elastic axis, positive in rearward direction
J	torsional stiffness constant	x_n	distance from foremost part of nose to elastic axis
k	radius of gyration of wing mass about elastic axis or elastic spring constant	x_t	distance from elastic axis to one-quarter-chord location on tail
l	length of section associated with a spanwise station	y	distance along wing measured from center of airplane
L	aerodynamic lift over interval l on wing	z	ratio of dynamic deflection to static deflection
L_f	shear force transmitted to wing by fuselage	α_t	angle of attack of horizontal tail, positive in the stalling direction
L_g	aerodynamic lift over interval l on wing due to gust	β	forward-speed and aspect-ratio factor for wing ($m_A \pi \rho U$) or coefficient of damping for spring oscillator
L_{g_t}	one-half aerodynamic lift on tail due to gust	β_t	forward-speed and aspect-ratio factor for tail
L_t	one-half total aerodynamic lift on tail		$\left(\frac{1}{2} m_{A_t} \pi \rho S_t U\right)$
L_1	part of aerodynamic lift over interval l on wing (see equation (16))	γ	exponential coefficient in Φ function associated with time t
L_2	part of aerodynamic lift over interval l on wing (see equation (17))		$\left(\gamma = \frac{2U}{c_o} \lambda\right)$
m	mass of beam included in interval l or concentrated mass in spring oscillator	δ	coefficient of fuselage modal function
$\bar{m}$	mass m including apparent mass effect $\left(m + \frac{\pi \rho l c^2}{4}\right)$	ϵ	time interval
m_A	assumed over-all compressibility and aspect-ratio correction for wing $\left(\frac{A}{2 + A\sqrt{1-M^2}}\right)$	λ	exponential coefficient in Φ function associated with variable s
m_{A_t}	assumed over-all compressibility and aspect-ratio correction for horizontal tail $\left(\frac{A_t}{2 + A_t\sqrt{1-M^2}}\right)$	λ_t	dimensionless interval between $i-1$ and i stations ($\lambda_t b$ is actual length)
$\bar{m}_e$	mass moment m_e including apparent mass effect $\left(m_e + \frac{\pi \rho l c^3}{4} \left(\frac{1}{2} - \frac{a}{c}\right)\right)$	ρ	mass density of air
m_f	mass of fuselage per unit length	φ	angle of twist of wing, positive in stalling direction
$\bar{m}k^2$	mass polar moment of inertia mk^2 including apparent mass effects $\left(mk^2 + \frac{\pi \rho l c^4}{4} \left(\frac{1}{2} - \frac{a}{c}\right)^2 + \frac{\pi \rho l c^4}{128}\right)$	ψ	function which denotes growth of lift on rigid airfoil entering sharp-edge gust (used without subscript to indicate function for wing and with subscript t used to indicate function for tail)
M	Mach number or aerodynamic moment over interval l about elastic axis of wing	ω_f	natural frequency associated with W_1 , radians per second
M_f	moment transmitted to wing by fuselage	$I(t)$	unit-step function
n	integers 0, 1, 2, 3, and so forth to designate number of time intervals passed	$1-\Phi$	function which denotes growth of lift on airfoil following sudden change in angle of attack (used without subscript to indicate function for wing and with subscript t used to indicate function for tail)
p	normal load acting at a station	$\begin{bmatrix} & \end{bmatrix}$	square matrix
p_f	fuselage inertia loading per unit length	$\begin{bmatrix} & \\ & \end{bmatrix}$	rectangular matrix
q	torsional load acting at a station	$\begin{bmatrix} \\ & \end{bmatrix}$	column matrix
s	distance traveled by wing in half-chords $\left(\frac{2U}{c_o} t\right)$, where midspan chord c_o is used as reference chord	$\begin{bmatrix} \\ & \\ & \end{bmatrix}$	row matrix
Δs	distance interval in half-chords $\left(\frac{2U}{c_o} \epsilon\right)$	Subscripts:	
S_t	horizontal-tail area	t	tail
t, τ	time, zero at beginning of gust penetration	0, 1, 2, 3, . . . n	number of time intervals passed
U	forward velocity of flight	0, 1, 2, 3, 4, 5 or i	station (however, station is usually given as parenthetical number, such as $w(3)$ for deflection at station 3); i is also used as general subscript in appendix A
v	vertical velocity of gust		

All the terms, coefficients, and matrices not defined in this section are defined in appendix A.

Dots are used to indicate derivatives with respect to time; for example, $\frac{\partial w}{\partial t} = \dot{w}$ or $\frac{\partial w}{\partial \tau} = \dot{w}$.

ANALYSIS

TRANSIENT RESPONSE OF A SIMPLE DAMPED OSCILLATOR

In order to illustrate the use of difference equations and to test the accuracy of the procedure that is to be used in the solution of the more complicated gust problems, the solution of a simple problem having a known analytical solution is first presented. The problem is to compute the response of the damped oscillator shown in figure 1 to a suddenly applied force. The differential equation of motion of this system due to the suddenly applied force is

$$m\ddot{w} + \beta\dot{w} + kw = FI(t) \quad (1)$$

By use of difference equations this differential equation may be transformed into an equation which involves deflection ordinates at several successive values of time. Probably the most commonly used difference equations are the following (see appendix B for derivation):

$$\dot{w}_n = \frac{w_{n+1} - w_{n-1}}{2\epsilon} \quad (2)$$

$$\ddot{w}_n = \frac{w_{n+1} - 2w_n + w_{n-1}}{\epsilon^2} \quad (3)$$

which give the derivatives at the intermediate of three successive ordinates. Although these equations are quite adequate for the oscillator problem of the present report, they cannot be used in the gust analysis which follows. Rather, for reasons which are brought out in a subsequent part of the analysis, equations that give the derivatives at the end ordinate of several successive ordinates must be used. If only three successive ordinates are used, the derivatives so found are not accurate enough to be useful. If a fourth ordinate is added, however, derivatives may be taken at the end ordinate with accuracies which are comparable to those given by equations (2) and (3). Such derivatives are derived also in appendix B and are given by the equations:

$$\dot{w}_n = \frac{11w_n - 18w_{n-1} + 9w_{n-2} - 2w_{n-3}}{6\epsilon} \quad (4)$$

$$\ddot{w}_n = \frac{2w_n - 5w_{n-1} + 4w_{n-2} - w_{n-3}}{\epsilon^2} \quad (5)$$

Although either equations (2) and (3) or equations (4) and (5) may be used in the solution of this oscillator problem, only equations (4) and (5) will be used, since only these equations can be used in the gust-problem solution presented in this report.

If the derivatives in equation (1) are replaced by the

FIGURE 1.—Damped oscillator and suddenly applied force.

difference equations (4) and (5), the following equation is obtained:

$$\left(2 + \frac{11}{6} \frac{\beta\epsilon}{m} + \frac{k}{m} \epsilon^2\right) w_n = \left(5 + \frac{3\beta\epsilon}{m}\right) w_{n-1} - \left(4 + \frac{9\beta\epsilon}{6m}\right) w_{n-2} + \left(1 + \frac{2\beta\epsilon}{6m}\right) w_{n-3} + \frac{\epsilon^2 F}{m} \quad (6)$$

This equation may be said to be the difference equation of motion. If the more general case of a variable applied force were being considered, the factor F in this equation would be replaced by F_n , the value of the force present at the time $t = n\epsilon$.

If a specific case is now considered, in which $\frac{k}{m} = 400$, $\frac{\beta}{2m} = 2$, $\epsilon = 0.01$, $F = 1$, and the notation $z = \frac{w}{F/k}$ (ratio of dynamic deflection to static deflection) is used, equation (6) becomes

$$z_n = 0.018927 + 2.42272 z_{n-1} - 1.92114 z_{n-2} + 0.47949 z_{n-3} \quad (7)$$

This equation may be regarded as a recurrence formula; the value z_n may be interpreted as the deflection to come and may be found easily from the three preceding deflections z_{n-1} , z_{n-2} , and z_{n-3} . Then with the newly found value z_n and with z_{n-1} and z_{n-2} , the next deflection can be found, and so on. This process thus gives a step-by-step derivation of the time history of deflection and may be carried out as far as is desired. Of course the process must start with known initial values of z . These values can be found with the aid of the initial conditions of the problem by means of the following approach.

The difference equations for the first and second derivatives at the third ordinate of four successive ordinates are (see appendix B)

$$\dot{w}_n = \frac{1}{6\epsilon} (2w_{n+1} + 3w_n - 6w_{n-1} + w_{n-2})$$

$$\ddot{w}_n = \frac{1}{\epsilon^2} (w_{n+1} - 2w_n + w_{n-1})$$

If these equations are taken to apply at $t=0$ ($n=0$), they become

$$\dot{w}_0 = \frac{1}{6\epsilon} (2w_1 + 3w_0 - 6w_{-1} + w_{-2}) \quad (8)$$

$$\ddot{w}_0 = \frac{1}{\epsilon^2} (w_1 - 2w_0 + w_{-1}) \quad (9)$$

For the problem under consideration the primary initial conditions are that, at $t=0$, the displacement and velocity are zero. By use of equation (1) or by reasoning from Newton's second law, a secondary initial condition can be established—that is, the acceleration immediately following the application of the unit force must be $1/m$. In equation form these conditions are

$$w_0=0$$

$$\dot{w}_0=0$$

$$\ddot{w}_0=\frac{1}{m}$$

By substitution of these values into equations (8) and (9) and by use of the notation $z=\frac{w}{F/k}$, the following relations can be found to exist between the ordinates:

$$\left. \begin{aligned} z_0 &= 0 \\ z_{-2} &= 0.24 - 8z_1 \\ z_{-1} &= 0.04 - z_1 \end{aligned} \right\} \quad (10)$$

Substitution of these values into equation (7), with n set equal to 1, gives an equation from which z_1 , the deflection at $t=\epsilon$, may be evaluated. Three successive deflections can now be established: the deflection at $t=\epsilon$, the zero deflection at $t=0$, and a fictitious deflection for $t=-\epsilon$ given by equation (10). In the real problem no deflection exists for t less than zero; the assumption that a deflection does exist before t is zero is simply a means for allowing the recurrence formula, equation (7), to apply at the origin as well as at later values of time. Furthermore, no violation is made of the conditions under consideration because, mathematically, the response after $t=0$ is not influenced by the response that may exist before $t=0$, so long as the initial conditions are satisfied. The process just described for treating the initial conditions is actually not different from the procedure commonly employed in difference-equation approaches, in which exterior points near a region under consideration are written in terms of the interior points by means of the boundary conditions.

With the initial values of deflection thus established the

FIGURE 2.—Comparison of exact and difference-equation solutions for response of damped oscillator.

step-by-step evaluation of succeeding deflections proceeds in a straight-forward manner—that is, equation (7) is now evaluated for $n=2$, then for $n=3$, and so on. The response of the oscillator for the physical constants listed previously is given in figure 2. The comparison between the difference solution shown in this figure and the exact solution of equation (1) is seen to be good. As a matter of interest, the solution is also shown in this figure that is obtained by the use of the parabolic end-ordinate derivative which involves only three successive ordinates. The agreement in this case is seen to be quite bad. If equations (2) and (3) had been used, on the other hand, the difference solution (in this case for w_{n+1}) would correspond to that given for the cubic end-ordinate derivative.

RECURRENCE MATRIX EQUATION FOR RESPONSE OF AN AIRPLANE IN A GUST

In order to help the reader to obtain a perspective of what is to be covered in this section, the following basic phases of the analysis are given:

- (1) The assumptions are stated.
- (2) The coordinate system and displacements are defined.
- (3) The aerodynamic lift and moment are defined.
- (4) The normal and torsional dynamic loadings (inertia forces, aerodynamic forces, and fuselage forces) on the wing are derived.
- (5) The equations of elastic deformation—wing vertical motion, wing rotation, and fuselage bending—are given.
- (6) The dynamic loadings on the wing are transformed into difference equations.
- (7) The equations of elastic deformation and the difference equations for loading are combined to give the recurrence matrix equation for response.

In succeeding sections the initial response is determined, the method for evaluating the gust forces is shown, and the method for computing the loads and stresses is indicated.

Assumptions.—In this analysis an attempt is made to obtain the simplest and most direct solution to the problem with a minimum of simplifying assumptions. The case treated is that of an airplane having an essentially straight wing and penetrating a gust of known structure. The tail is considered to penetrate subsequently the same gust as does the wing. The assumptions made are as follows:

Assumptions pertaining to elasticity and airplane motion:

- (1) The usual assumptions of engineering beam theory are made.
- (2) The fuselage is free to pitch and move vertically. The portion of the fuselage in front of the elastic axis of the wing is assumed for convenience to be rigid. The portion of the fuselage rearward of the elastic axis is assumed flexible, and the elastic deflection is assumed to be given by a single modal function.
- (3) The tail is assumed rigid.

Assumptions pertaining to aerodynamic forces:

- (1) Aerodynamic strip theory applies. Three-dimensional effects, however, may be taken into account approximately by means of over-all corrections. Some such corrections are indicated.
- (2) The gust force and forces due to vertical and pitching motion are the only tail forces considered. Other forces of known character may be included, however, if desired.

(3) Aerodynamic forces on the fuselage are neglected.

Coordinate system and displacements.—Position on the airplane is denoted by an orthogonal system of axes. The origin is at the intersection of the wing elastic axis with the plane of symmetry of the airplane: the w -axis runs positive upward, the x -axis runs along the fuselage positive in the rearward direction, and the y -axis runs spanwise. The wing semispan is considered to be divided into six, not necessarily equal, sections, with a station point at the middle of each section. (See fig. 3.) More or fewer stations could be chosen, but it is believed that six is a fair compromise between the amount of labor involved in setting up a solution and the accuracy desired. The interval between stations is designated by the number of the station at the outboard end of the interval. Station 0 is located near the wing root and generally may be located where the fuselage intersects the wing. In this way the concentrated forces of the fuselage are allowed to act through station 0. The other five stations are then located in any convenient manner so as to fall at concentrated mass locations or at points which represent the average of distributed masses, station 5 being nearest the tip. The total mass within a section is assumed to be concentrated at the station point, and the average of the section geometry (chord, elastic axis position, and so on) is assumed to apply. In this way the wing is assumed to be a beam subject to six load concentrations and as such will have a linear moment variation between each station. The further assumption is made that the $\frac{1}{EI}$ variation is linear between each station. With these assumptions for the EI variation and concentrated load locations, equations for deflection at each station point may be derived (appendix C) by direct analytical treatment.

The displacements of the cross section at each station of the wing are given as the deflection of and rotation about the wing elastic axis as shown in figure 4. The fuselage displacements are shown in figure 5 and are given by the equations:

$$w_f = w(0) - \varphi(0)x \quad (11)$$

for the forward section and

$$w_f = w(0) - \varphi(0)x + W_1\delta \quad (12)$$

for the rearward section. The function W_1 is taken as the fundamental mode of vibration of the fuselage and tail assembly, when the fuselage is considered to be clamped as a cantilever beam at the elastic-axis location of the wing, and is given in terms of a unit deflection at the $\frac{1}{4}$ -chord position on the tail. With this function to represent the elastic deformation of the fuselage the deflection and angle of attack of the tail are found with the aid of equation (12) to be

$$w_f(x_t) = w(0) - \varphi(0)x_t + \delta \quad (13)$$

$$\alpha_t = -\left.\frac{dw_f}{dx}\right|_{x=x_t} = \varphi(0) - \delta\theta_1 \quad (14)$$

where

$$\theta_1 = \left.\frac{dW_1}{dx}\right|_{x=x_t}$$

FIGURE 3.—Division of wing into sections.

FIGURE 4.—Displacements of a wing cross section.

FIGURE 5.—Coordinate system for fuselage displacement.

Aerodynamic lift and moment.—Before going into the details of the analysis it is felt worthwhile to define and describe the nature of the aerodynamic forces to which the wing is subjected. These forces originate from two sources: they arise directly from the gust encountered, and they arise from the ensuing airplane motion. The equations for the aerodynamic lift and moment that develop are herein set up in a convenient form on the basis of work given in references 1 to 4. In these investigations various methods for separating the lift forces have been used, but the particular method for separating these forces is not important so long as they are taken into account properly.

In the present report the aerodynamic lift and moment are considered to be composed of two parts: one part, designated as the lift or moment due to circulation, which includes all lift forces or moments exclusive of aerodynamic inertia effects and the other part, which is due solely to these inertia effects. These lift forces and moments can be resolved into the force systems acting on the airfoil as shown in sketch 1 (forces due to circulation) and sketch 2 (inertia force and moment).

SKETCH 1.

SKETCH 2.

The force L_g is the lift force developed by the gust and corresponds to the gust force that would develop on the airfoil considered rigid and restrained against vertical motion. All the other forces occur as a result of motion of the airfoil. These forces, as well as the gust force, are given for an interval l of the span by the equations: For the forces due to circulation,

$$L_g = m_A \pi \rho c l U \int_0^t \frac{\partial v}{\partial \tau} \psi(t-\tau) d\tau \quad (15)$$

$$L_1 = m_A \pi \rho c l U \int_0^t \left[U \dot{\Phi} - \ddot{w} + c \left(\frac{3}{4} - \frac{a}{c} \right) \ddot{\psi} \right] [1 - \Phi(t-\tau)] d\tau \quad (16)$$

$$\bar{L}_2 = \frac{m_A \pi \rho l c^2}{4} U \dot{\Phi} \quad (17)$$

and for the inertia force and moment,

$$L_3 = \frac{\pi \rho l c^2}{4} \left[-\ddot{w} + \left(\frac{c}{2} - a \right) \ddot{\psi} \right] \quad (18)$$

$$M_1 = -\frac{\pi \rho l c^4}{128} \ddot{\psi} \quad (19)$$

where

m_A factor which can be used to introduce over-all compressibility and aspect-ratio corrections; in this report the factor is assumed to be given by

$$\frac{A}{2 + A\sqrt{1-M^2}}$$

$1-\Phi$ lift function which denotes the growth of lift on an airfoil following a sudden change in angle of attack

ψ lift function which denotes the growth of lift on a rigid airfoil entering a sharp-edge gust

The functions $1-\Phi$ and ψ and the correction m_A are established as follows. In reference 5, approximate equations are derived which give the lift-coefficient form of the growth of lift on a finite wing following a sudden change in angle of attack or due to the penetration of a sharp-edge gust. The equations may conveniently be considered as the product of a factor, which may be regarded as a lift-curve slope, and an unsteady lift function, designated by $1-\Phi$ for the function due to the angle-of-attack change and by ψ for the function due to the sharp-edge gust. These unsteady lift functions are shown in figures 6 and 7 and are given by the following equations: For the $1-\Phi$ functions

$$(1-\Phi)_{A=3} = 1 - 0.283e^{-0.540s} \quad (20a)$$

$$(1-\Phi)_{A=6} = 1 - 0.361e^{-0.381s} \quad (20b)$$

$$(1-\Phi)_{A=\infty} = 1 - 0.165e^{-0.045s} - 0.335e^{-0.300s} \quad (20c)$$

and for the ψ functions

$$\psi_{A=3} = 1 - 0.679e^{-0.558s} - 0.227e^{-3.20s} \quad (21a)$$

$$\psi_{A=6} = 1 - 0.448e^{-0.290s} - 0.272e^{-0.725s} - 0.193e^{-3.00s} \quad (21b)$$

$$\psi_{A=\infty} = 1 - 0.236e^{-0.058s} - 0.513e^{-0.364s} - 0.171e^{-2.42s} \quad (21c)$$

$$\psi_{A=\infty} = 1 - 0.500e^{-0.130s} - 0.500e^{-s} \quad (22)$$

FIGURE 6.—Lift functions for sudden change in angle of attack. (See equations (20).)

FIGURE 7.—Lift functions for wings entering a sharp-edge gust. (See equations (21) and (22).)

Equations (21) are based on equations of reference 5; whereas equation (22) is the ψ function that is suggested for wings of infinite aspect ratio in reference 3. Inspection of equations (20) shows that the Φ function for aspect ratios 3 and 6 is given by a single exponential term. It is probable that the Φ function for higher aspect ratios, say 10 and even 20, may also be given to a sufficient approximation by a single exponential term. Therefore, the assumption is made that in general Φ may be represented by an equation of the form

$$\Phi = a_1 e^{-\lambda s} \quad (23)$$

Interpolation, for example, of the curves in figure 6 shows that the Φ function for aspect ratio 10 might be approximated by the equation:

$$\Phi_{A=10} = 0.41e^{-0.3s} \quad (24)$$

The analysis does not necessarily limit Φ to a single exponential term. Other terms could be added with some increase in labor, but the degree of refinement obtained is not expected to add much to the over-all accuracy of the solution.

Although the functions given by equations (20) to (22) are known to approximate the true functions quite well over a large range in s ($s = \frac{2U}{c_0} t$), the ψ functions given by

equations (21) do not vanish, as they should, when $t=0$. When used in the computational procedures given hereinafter, these functions, therefore, are to be taken as zero when $t=0$. Another point to note is that the variable s is given in terms of a reference chord c_0 ; thus this variable as applied to the wing is different, in general, from the variable as applied to the tail.

Examination of the values of lift-curve slope, which were stated to be present in the equations taken from reference 5, reveals that they may be approximated with good accuracy by the product of 2π and the often-used aspect-ratio correction $\frac{A}{A+2}$ for steady incompressible flow. In the present report it is assumed that compressibility and aspect-ratio corrections can be made by replacing this aspect-ratio correction by a compressible aspect-ratio correction defined by $\frac{A'}{A'+2}$, where $A' = A\sqrt{1-M^2}$, and by multiplying this correction by the Glauert-Prandtl Mach number correction $\frac{1}{\sqrt{1-M^2}}$ to give the product m_A . The procedure then for taking into account three-dimensional and compressibility effects in the present analysis is to determine m_A from the forward speed and aspect ratio of the wing and to use the $1-\Phi$ and ψ functions, equations (20) to (24), for the aspect ratio which is nearest that of the wing.

Some word of explanation of equation (16) might be worthwhile at this point. The $\Phi(t-\tau)$ function is associated with the lift forces which are due to the wake. Without this term the equation would yield the steady lift corresponding to the instantaneous values of angle of attack and vertical velocity. If equation (16) is integrated by parts and the conditions are stipulated that w , $\dot{w}$, φ , and $\dot{\varphi}$ are all zero at $t=0$, the following equation may be found:

$$L_1 = \beta c l \dot{\Phi}_0 w - (1 - \Phi_0) \beta c l \dot{w} + \beta c l U \left[1 - \Phi_0 - \frac{c}{U} \left(\frac{3}{4} - \frac{a}{c} \right) \dot{\Phi}_0 \right] \varphi + (1 - \Phi_0) \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) \dot{\varphi} + \beta c l \int_0^t w \ddot{\Phi}(t-\tau) d\tau - \beta c l U \int_0^t \varphi \dot{\Phi}(t-\tau) d\tau - \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) \int_0^t \varphi \ddot{\Phi}(t-\tau) d\tau \quad (25)$$

where β has been introduced as a forward-speed and aspect-ratio parameter defined by the equation

$$\beta = m_A \pi \rho U \quad (26)$$

With reference to equation (23), Φ_0 and $\dot{\Phi}_0$ in equation (25) would have the values

$$\Phi_0 = a_1$$

$$\dot{\Phi}_0 = -\frac{2U}{c_0} \lambda a_1$$

The form of L_1 given by equation (25) is presented because this form is more convenient to use in the present analysis.

For this analysis the total lift and moment acting at the elastic-axis location are desired. For the present, the total lift L and moment M of the forces due to circulation are found; the inertia force and moment are to be treated

separately. Summation of all the lift forces due to circulation and summation of the moments of these forces about the elastic axis gives the desired equations for the aerodynamic lift and moment acting on the airfoil over an interval l as follows:

$$L = L_1 + L_2 + L_3 \quad (27)$$

$$M = \left(a - \frac{c}{4} \right) L_1 - \left(\frac{3c}{4} - a \right) L_2 + \left(a - \frac{c}{4} \right) L_3 \quad (28)$$

The loading on the wing.—The normal and torsional dynamic loads that are held in equilibrium by the elastic restoring forces of the wing may be found by considering all the aerodynamic and inertia forces that act on the wing. The mass situated at any station (see fig. 4) can be shown to have an inertia normal force equal to

$$-m\ddot{w} + me\ddot{\varphi}$$

and an inertia torsional moment about the elastic axis equal to

$$me\ddot{w} - mk^2\ddot{\varphi}$$

If the aerodynamic forces and moments (see equations (18), (19), (27), and (28)) are added to these inertia loadings, the total normal and torsional loadings on the wing at each station are found to be given, respectively, by the equations:

$$p = -m\ddot{w} + me\ddot{\varphi} + L + L_3$$

$$q = me\ddot{w} - mk^2\ddot{\varphi} + M - \left(\frac{c}{2} - a \right) L_3 + M_1$$

The terms L_3 and M_1 ordinarily would appear with the aerodynamic lift and moment values but are treated separately so that they can be combined with the structural mass terms. If use is made of equations (18) and (19), the loading equations become

$$p = -\bar{m}\ddot{w} + \bar{m}e\ddot{\varphi} + L \quad (29)$$

$$q = \bar{m}e\ddot{w} - \bar{m}k^2\ddot{\varphi} + M \quad (30)$$

where

$$\bar{m} = \left(m + \frac{\pi \rho l c^2}{4} \right)$$

$$\bar{m}e = \left[me + \frac{\pi \rho l c^3}{4} \left(\frac{1}{2} - \frac{a}{c} \right) \right]$$

$$\bar{m}k^2 = \left[mk^2 + \frac{\pi \rho l c^4}{4} \left(\frac{1}{2} - \frac{a}{c} \right)^2 + \frac{\pi \rho l c^4}{128} \right]$$

The terms appearing with the structural mass quantities in the definitions of $\bar{m}$, $\bar{m}e$, and $\bar{m}k^2$ are the terms which are commonly associated with apparent mass effects.

The value of the shear forces L_f and the moment M_f transmitted to the wing by the fuselage can be found in the following manner. From equations (11) and (12) the values of the inertia loading on the forward and rearward sections of the fuselage can be shown to be given, respectively, by the equations:

$$p_f = -m_f [\ddot{w}(0) - \ddot{\varphi}(0)x] \quad (31)$$

$$p_f = -m_f [\ddot{w}(0) - \ddot{\varphi}(0)x + \ddot{\delta} W_1] \quad (32)$$

Integration of these inertia loadings over the length of the fuselage and addition of the aerodynamic tail load $2L_t$ give the value of the total load transmitted to the wing; one-half of this load is designated by L_f and is assumed to act at station 0, the other half being considered to act through the corresponding station on the other half of the wing. Integration of the moment of the inertia loading about the elastic-axis location and addition of the moment $-2x_t L_t$ of the tail forces give the total moment due to the fuselage; one-half of the moment is designated M_f and acts at station 0. The values of L_f and M_f thus found can be given by the equations:

$$L_f = -M_1 \ddot{w}(0) + M_2 \ddot{\varphi}(0) - M_3 \ddot{\delta} + L_t \quad (33)$$

$$M_f = M_2 \ddot{w}(0) - M_4 \ddot{\varphi}(0) + M_5 \ddot{\delta} - x_t L_t \quad (34)$$

where the M_i 's are considered to be generalized masses defined as follows:

$$\left. \begin{aligned} M_1 &= \frac{1}{2} \int_{x_n}^{x_t} m_f dx \\ M_2 &= \frac{1}{2} \int_{x_n}^{x_t} m_f x dx \\ M_3 &= \frac{1}{2} \int_0^{x_t} m_f W_1 dx \\ M_4 &= \frac{1}{2} \int_{x_n}^{x_t} m_f x^2 dx \\ M_5 &= \frac{1}{2} \int_0^{x_t} m_f x W_1 dx \\ M_6 &= \frac{1}{2} \int_0^{x_t} m_f W_1^2 dx \end{aligned} \right\} \quad (35)$$

The generalized mass constant M_6 , although not appearing in equations (33) or (34), is included in this group because it occurs in a subsequent part of the analysis. In the derivation of equation (34), the aerodynamic moment of the tail about the tail $\frac{1}{4}$ -chord position is neglected since it is considered to be small in comparison with the value $x_t L_t$. The lift on the tail L_t can be found by application of equation (27) to the tail surface. In this case the Φ function appropriate to the tail should be chosen and the values of displacement w and φ should be replaced by $w_f(x_t)$ and α_t , the values of deflection and angle of attack at the tail $\frac{1}{4}$ -chord position. These values are given by equations (13) and (14).

Matrix equation of equilibrium.—The problem of computing the response may be considered to be one of the determination of the deflection and rotation of a beam which is subjected to normal and torque loadings. In differential

form, the bending and rotational displacements are related to the normal and torque loadings by the well-known expressions:

$$\frac{\partial^2}{\partial y^2} EI \frac{\partial^2 w}{\partial y^2} = p \quad (36)$$

$$-\frac{\partial}{\partial y} GJ \frac{\partial \varphi}{\partial y} = q \quad (37)$$

where in this instance p and q are the loadings per unit length of beam. In addition to these two equations which are considered to apply to the wing, an equation for computing the elastic deformations of the fuselage may be found; this equation may be found in the following manner. The rearward part of the fuselage is considered to be a cantilever beam subjected to the inertia loading given by equation (32) and the tail force $2L_t$. If equation (36) is applied to the fuselage and use is made of equations (12) and (32), the following equation for fuselage bending results:

$$\delta \frac{\partial^2}{\partial x^2} EI_f \frac{\partial^2 W_1}{\partial x^2} = -m_f [\ddot{w}(0) - \ddot{\varphi}(0)x + \ddot{\delta} W_1] + 2L_t \quad (38)$$

in which L_t must be treated properly as a concentrated load and I_f is the bending moment of inertia of the fuselage. Since W_1 represents a vibration modal function, the following relation exists:

$$\frac{\partial^2}{\partial x^2} EI_f \frac{\partial^2 W_1}{\partial x^2} = m_f \omega_f^2 W_1$$

where ω_f is the frequency of vibration associated with W_1 . Equation (38) may therefore be written

$$\delta m_f \omega_f^2 W_1 = -m_f [\ddot{w}(0) - \ddot{\varphi}(0)x + \ddot{\delta} W_1] + 2L_t$$

Multiplication of this equation through by W_1 and integration between 0 and x_t results in the following equation for fuselage bending

$$\omega_f^2 M_6 \delta = -M_3 \ddot{w}(0) + M_5 \ddot{\varphi}(0) - M_6 \ddot{\delta} + L_t \quad (39)$$

where M_3 , M_5 , and M_6 are defined by equations (35).

Equations (36), (37), and (39), when the loadings given by equations (29) and (30) are considered, are seen to be rather involved integrodifferential equations but describe completely the motion of the airplane. The problem is to find functions w , φ , and δ which satisfy these equations and which satisfy both the boundary conditions and the initial conditions.

The problem of finding the w and φ functions may be simplified considerably by reducing the rather complicated equations of motion to a simplified and systematic algebraic form. The first step (see appendix C) is to replace the differential equations (36) and (37) for wing deflection and wing rotation by the following simple matrix equations:

$$[A] |w| = |p| \quad (40)$$

$$[B] |\varphi| = |q| \quad (41)$$

The matrices in these equations are defined in appendix C (see equations (C22) and (C23) and equations (C29) and (C30), respectively) and have been derived on the basis that the displacements along the semispan are given at six stations.

Equations (40) and (41) and the fuselage deflection coefficient δ are now combined in a single matrix equation of the form indicated as follows:

$$\begin{bmatrix} 0 & 0 & 0 \\ 0 & [A] & 0 \\ 0 & 0 & [B] \end{bmatrix} \begin{bmatrix} \delta \\ |w| \\ |\varphi| \end{bmatrix} = \begin{bmatrix} 0 \\ |p| \\ |q| \end{bmatrix} \quad (42)$$

This form is chosen because it will be useful subsequently. With the notation given in appendix A, equation (42) may be abbreviated to the form:

$$[C] \begin{bmatrix} \delta \\ w \\ \varphi \end{bmatrix} = [P] \quad (43)$$

This equation may be regarded as the loading matrix equation of equilibrium; it relates the loadings to the displacements by linear simultaneous equations. The boundary conditions are automatically satisfied when this equation is used because they had to be taken into account when the submatrices $[A]$ and $[B]$ were derived. Only the initial conditions remain to be satisfied and these are treated separately in a subsequent section.

Transformation of the loading equations into difference form.—The loading equations are now simplified by replacing the time derivatives by difference equations. If equation (5) is used to replace the derivative in equations (29) and (30), the values of the loading at the n th time interval are found to be

$$p_n = -\frac{\bar{m}}{\epsilon^2} (2w_n - 5w_{n-1} + 4w_{n-2} - w_{n-3}) + \frac{\bar{m}e}{\epsilon^2} (2\varphi_n - 5\varphi_{n-1} + 4\varphi_{n-2} - \varphi_{n-3}) + L_n \quad (44)$$

$$q_n = \frac{\bar{m}e}{\epsilon^2} (2w_n - 5w_{n-1} + 4w_{n-2} - w_{n-3}) - \frac{\bar{m}k^2}{\epsilon^2} (2\varphi_n - 5\varphi_{n-1} + 4\varphi_{n-2} - \varphi_{n-3}) + M_n \quad (45)$$

The values L_n and M_n are found by determining the expressions for L_1 , L_2 , and L_g at $t=n\epsilon$ (see equations (27) and (28)). Of these L_1 is the most complicated, since it (see equation (25)) involves three unsteady lift integrals of the Duhamel type. Fortunately, however, a rather simple recurrence relation can be developed which allows the calculation of the value of these integrals at a given time interval directly from the value at the previous time interval. This derivation is presented in appendix D and is made possible because the Φ function is of an exponential form. (Where the Φ function is given by more than one exponential term, a recurrence

relation for each term may be written.) From the derivation in appendix D, therefore, the value of the three integrals at the n th time interval may be given as follows:

$$F_n + \frac{\beta c l \epsilon}{2} \ddot{\Phi}_0 w_n - \frac{\beta c l \epsilon}{2} \left[U \dot{\Phi}_0 + c \left(\frac{3}{4} - \frac{a}{c} \right) \ddot{\Phi}_0 \right] \varphi_n \quad (46)$$

where

$$F_n = e^{-\gamma \epsilon} F_{n-1} + g w_{n-1} + g' \varphi_{n-1}$$

in which g and g' are defined by equations (A5) in appendix A. With this expression to replace the value of the integrals in equation (25), the value of L_{1n} may be written

$$\begin{aligned} L_{1n} = & \beta c l \left(\dot{\Phi}_0 + \frac{\epsilon}{2} \ddot{\Phi}_0 \right) w_n - (1 - \Phi_0) \beta c l \dot{w}_n + \\ & \beta c l \left[U(1 - \Phi_0) - \frac{\epsilon U}{2} \dot{\Phi}_0 - \left(\dot{\Phi}_0 + \frac{\epsilon}{2} \ddot{\Phi}_0 \right) c \left(\frac{3}{4} - \frac{a}{c} \right) \right] \varphi_n + \\ & (1 - \Phi_0) \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) \dot{\varphi}_n + F_n \end{aligned} \quad (47)$$

With the use of difference equation (4), this equation may be transformed finally into the form:

$$\begin{aligned} L_{1n} = & d_0 w_n + d_1 w_{n-1} + d_2 w_{n-2} + d_3 w_{n-3} + d_0' \varphi_n + \\ & d_1' \varphi_{n-1} + d_2' \varphi_{n-2} + d_3' \varphi_{n-3} + F_n \end{aligned} \quad (48)$$

where the d 's are defined in appendix A. Likewise, from equations (4), (17), and (26), L_{2n} may be written

$$L_{2n} = \frac{\beta l c^2}{24 \epsilon} (11 \varphi_n - 18 \varphi_{n-1} + 9 \varphi_{n-2} - 2 \varphi_{n-3})$$

If L_{1n} , L_{2n} , and the value L_{gn} of the gust force at $t=n\epsilon$ are introduced into equation (44), the value of p at the n th time interval can be shown to be given by the equation:

$$\begin{aligned} p_n = & \eta_0 w_n + \eta_1 w_{n-1} + \eta_2 w_{n-2} + \eta_3 w_{n-3} + \eta_0' \varphi_n + \\ & \eta_1' \varphi_{n-1} + \eta_2' \varphi_{n-2} + \eta_3' \varphi_{n-3} + F_n + L_{gn} \end{aligned} \quad (49)$$

where the η 's are coefficients which are given by equations (A3) in appendix A. In a similar manner, the equation for q (equation (45)) can be reduced to the form:

$$\begin{aligned} q_n = & \nu_0 w_n + \nu_1 w_{n-1} + \nu_2 w_{n-2} + \nu_3 w_{n-3} + \nu_0' \varphi_n + \nu_1' \varphi_{n-1} + \\ & \nu_2' \varphi_{n-2} + \nu_3' \varphi_{n-3} + \left(a - \frac{c}{4} \right) F_n + \left(a - \frac{c}{4} \right) L_{gn} \end{aligned} \quad (50)$$

where the ν 's are given by equations (A4) in appendix A.

The value of aerodynamic lift acting at the tail $\frac{1}{4}$ -chord L_t is found most conveniently by applying equation (49) to one-half of the tail surface. This application is made by modifying the η coefficients as follows: The mass value m is set equal to zero, $\frac{a}{c}$ is taken as $\frac{1}{4}$, c is replaced by c_t , and

β_{cl} is replaced by β_t , defined as the forward-speed and aspect-ratio parameter of the tail by the equation:

$$\beta_t = \frac{1}{2} m_{A_t} \pi \rho U S_t \quad (51)$$

In addition, w and φ are replaced by the deflection and rotation of the tail given by equations (13) and (14). With these substitutions the value of L_{t_n} is found to be

$$\begin{aligned} L_{t_n} = & f_0 w(0)_n + f_1 w(0)_{n-1} + f_2 w(0)_{n-2} + f_3 w(0)_{n-3} + f_0' \varphi(0)_n + \\ & f_1' \varphi(0)_{n-1} + f_2' \varphi(0)_{n-2} + f_3' \varphi(0)_{n-3} + \bar{f}_0 \delta_n + \bar{f}_1 \delta_{n-1} + \\ & \bar{f}_2 \delta_{n-2} + \bar{f}_3 \delta_{n-3} + F_{t_n} + L_{g_{t_n}} \end{aligned} \quad (52)$$

where

$$F_{t_n} = e^{-\gamma_t \epsilon} F_{t_{n-1}} + j w(0)_{n-1} + j' \varphi(0)_{n-1} + \bar{j} \delta_{n-1} \quad (53)$$

$L_{g_{t_n}}$ is one-half the tail gust force at $t = n\epsilon$ and the f 's and j 's are defined by equations (A7) and (A11), respectively, in appendix A.

With equation (52) and difference equation (5), equations (33) and (34) for L_f and M_f and equation (39) for fuselage bending may be reduced readily to the following form:

$$\begin{aligned} L_{f_n} = & \gamma_0 w(0)_n + \gamma_1 w(0)_{n-1} + \gamma_2 w(0)_{n-2} + \gamma_3 w(0)_{n-3} + \gamma_0' \varphi(0)_n + \\ & \gamma_1' \varphi(0)_{n-1} + \gamma_2' \varphi(0)_{n-2} + \gamma_3' \varphi(0)_{n-3} + \bar{\gamma}_0 \delta_n + \bar{\gamma}_1 \delta_{n-1} + \\ & \bar{\gamma}_2 \delta_{n-2} + \bar{\gamma}_3 \delta_{n-3} + F_{t_n} + L_{g_{t_n}} \end{aligned} \quad (54)$$

$$\begin{aligned} M_{f_n} = & \mu_0 w(0)_n + \mu_1 w(0)_{n-1} + \mu_2 w(0)_{n-2} + \mu_3 w(0)_{n-3} + \mu_0' \varphi(0)_n + \\ & \mu_1' \varphi(0)_{n-1} + \mu_2' \varphi(0)_{n-2} + \mu_3' \varphi(0)_{n-3} + \bar{\mu}_0 \delta_n + \bar{\mu}_1 \delta_{n-1} + \\ & \bar{\mu}_2 \delta_{n-2} + \bar{\mu}_3 \delta_{n-3} - x_t F_{t_n} - x_t L_{g_{t_n}} \end{aligned} \quad (55)$$

$$\begin{aligned} 0 = & r_0 w(0)_n + r_1 w(0)_{n-1} + r_2 w(0)_{n-2} + r_3 w(0)_{n-3} + r_0' \varphi(0)_n + \\ & r_1' \varphi(0)_{n-1} + r_2' \varphi(0)_{n-2} + r_3' \varphi(0)_{n-3} + \bar{r}_0 \delta_n + \bar{r}_1 \delta_{n-1} + \\ & \bar{r}_2 \delta_{n-2} + \bar{r}_3 \delta_{n-3} + F_{t_n} + L_{g_{t_n}} \end{aligned} \quad (56)$$

where the γ 's, μ 's, and r 's are given by equations (A8) to (A10) in appendix A.

The complete set of loading equations as well as the fuselage bending equations are now available in difference form. Equations (49) and (50) apply at each spanwise station and in addition the values of L_f and M_f must be introduced at station 0. The coefficients η , ν , γ , and so forth are seen to involve only the physical properties of the airplane structure, the forward-speed and aspect-ratio parameters given by equations (26) and (51), certain constants derived from the unsteady lift function, and the time interval. The time interval ϵ that is chosen should be fairly small in comparison with the natural period of the fundamental mode in bending of the wing. To serve as a guide an interval chosen near 1/30 of the estimated period of vibration of the fundamental mode appears to be quite satisfactory. Of course, some caution should be observed

in the choice of this interval if the airplane is near a critical condition where some mode other than the fundamental may predominate. For example, if the airplane is flying near the flutter speed, the characteristic frequency of the response may be near the natural torsional frequency of the wing. The time interval should be modified accordingly.

Recurrence matrix equation for response.—Equations (49), (50), (54), and (55) for loading, equation (56) for fuselage bending, and the equilibrium equation (43) may now be combined to give the recurrence matrix equation for response. In order to simplify the process of combining these equations, only the abbreviated or symbolic form of the matrices which occur are used. The definitions of these matrices are given, unless otherwise stated, in a complete group in appendix A.

Application of equations (49) and (50) to each of the spanwise stations and of equations (54) and (55) to station 0 leads to a set of loading equations which may be put in the matrix form given by the following equations:

$$\begin{aligned} |p|_n = & |\bar{\gamma}_0| \delta_n + |\bar{\gamma}_1| \delta_{n-1} + |\bar{\gamma}_2| \delta_{n-2} + |\bar{\gamma}_3| \delta_{n-3} + [\eta_0] |w|_n + \\ & [\eta_1] |w|_{n-1} + [\eta_2] |w|_{n-2} + [\eta_3] |w|_{n-3} + [\eta_0'] |\varphi|_n + \\ & [\eta_1'] |\varphi|_{n-1} + [\eta_2'] |\varphi|_{n-2} + [\eta_3'] |\varphi|_{n-3} + |F| + |L_g| \Big|_n + \\ & |1| (F_t + L_{g_t})_n \end{aligned} \quad (57)$$

$$\begin{aligned} |q|_n = & |\bar{\mu}_0| \delta_n + |\bar{\mu}_1| \delta_{n-1} + |\bar{\mu}_2| \delta_{n-2} + |\bar{\mu}_3| \delta_{n-3} + [\nu_0] |w|_n + \\ & [\nu_1] |w|_{n-1} + [\nu_2] |w|_{n-2} + [\nu_3] |w|_{n-3} + [\nu_0'] |\varphi|_n + \\ & [\nu_1'] |\varphi|_{n-1} + [\nu_2'] |\varphi|_{n-2} + [\nu_3'] |\varphi|_{n-3} + \left[a - \frac{c}{4} \right] |F| + \\ & |L_g| \Big|_n + |x_t| (F_t + L_{g_t})_n \end{aligned} \quad (58)$$

where

$$|F|_n = e^{-\gamma_t \epsilon} |F|_{n-1} + [g] |w|_{n-1} + [g'] |\varphi|_{n-1} \quad (59)$$

$$(F_t)_n = e^{-\gamma_t \epsilon} (F_t)_{n-1} + j w(0)_{n-1} + j' \varphi(0)_{n-1} + \bar{j} \delta_{n-1} \quad (60)$$

Equations (57) and (58) and equation (56) may now be combined to form the following matrix equation:

$$\begin{aligned} \begin{bmatrix} 0 \\ |p| \\ |q| \end{bmatrix}_n = & \begin{bmatrix} \bar{\gamma}_0 & [r_0] & [r_0'] \\ |\bar{\gamma}_0| & [\eta_0] & [\eta_0'] \\ |\bar{\mu}_0| & [\nu_0] & [\nu_0'] \end{bmatrix} \begin{bmatrix} \delta \\ |w| \\ |\varphi| \end{bmatrix}_n + \begin{bmatrix} \bar{\gamma}_1 & [r_1] & [r_1'] \\ |\bar{\gamma}_1| & [\eta_1] & [\eta_1'] \\ |\bar{\mu}_1| & [\nu_1] & [\nu_1'] \end{bmatrix} \begin{bmatrix} \delta \\ |w| \\ |\varphi| \end{bmatrix}_{n-1} + \\ & \begin{bmatrix} \bar{\gamma}_2 & [r_2] & [r_2'] \\ |\bar{\gamma}_2| & [\eta_2] & [\eta_2'] \\ |\bar{\mu}_2| & [\nu_2] & [\nu_2'] \end{bmatrix} \begin{bmatrix} \delta \\ |w| \\ |\varphi| \end{bmatrix}_{n-2} + \begin{bmatrix} \bar{\gamma}_3 & [r_3] & [r_3'] \\ |\bar{\gamma}_3| & [\eta_3] & [\eta_3'] \\ |\bar{\mu}_3| & [\nu_3] & [\nu_3'] \end{bmatrix} \begin{bmatrix} \delta \\ |w| \\ |\varphi| \end{bmatrix}_{n-3} + \\ & \begin{bmatrix} 1 & 0 \\ |1| & [I] \\ |x_t| & \left[a - \frac{c}{4} \right] \end{bmatrix} \begin{bmatrix} F_t + L_{g_t} \\ |F| + |L_g| \\ \end{bmatrix}_n \end{aligned} \quad (61)$$

For simplicity, this equation may be abbreviated to the form:

$$[P]_n = [S_0] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_n + [S_1] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-1} + [S_2] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-2} + [S_3] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-3} + [R] \begin{Bmatrix} \bar{F} \\ \bar{L}_g \end{Bmatrix}_n \quad (62)$$

where

$$[\bar{F}]_n = [e] [\bar{F}]_{n-1} + [W] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-1} \quad (63)$$

and the matrix $[\bar{L}_g]_n$ is defined in the section entitled "Derivation of Gust Forces."

Substitution of equation (62) in equation (43) gives

$$[C] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_n = [S_0] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_n + [S_1] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-1} + [S_2] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-2} + [S_3] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-3} + [R] \begin{Bmatrix} \bar{F} \\ \bar{L}_g \end{Bmatrix}_n \quad (64)$$

With the use of the notations

$$[D] = [C] - [S_0] \quad (65)$$

and

$$[Q]_n = [S_1] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-1} + [S_2] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-2} + [S_3] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_{n-3} + [R] \begin{Bmatrix} \bar{F} \\ \bar{L}_g \end{Bmatrix}_n \quad (66)$$

equation (64) may be written simply

$$[D] \begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_n = [Q]_n \quad (67)$$

Multiplying through by the reciprocal of $[D]$ gives finally the equation

$$\begin{Bmatrix} \delta \\ w \\ \varphi \end{Bmatrix}_n = [D]^{-1} [Q]_n \quad (68)$$

This equation gives the displacements that apply at time n in terms of the displacements that occurred at several preceding values of time (see equations (63) and (66) for the definitions of $[\bar{F}]_n$ and $[Q]_n$).

From equation (68) the complete response of the airplane can be computed once the character of the gust is known. The matrix of gust-force values $[\bar{L}_g]_n$ can be determined by the procedure given in the section entitled "Derivation of Gust Forces." The initial conditions (treated in the following section) are used to obtain three successive initial sets of the displacements. With these sets of displacements the next set may be obtained by application of equation (68). With the newly found set and the preceding sets of displacements, the next set may then be found, and so forth, until a sufficient time history of the displacements is found from which maximum loading conditions may be determined.

The reason for using the difference form of the derivatives as given by equations (4) and (5) might now be given. Equation (64) may be considered a differential equation, since the matrix $[C]$ contains the spanwise derivative matrices $[A]$ and $[B]$ and may be likened to the differential equation which relates the load to the deflection for a beam. The unknowns are the deflections at time n . The right-hand terms correspond to the loading, the first term being the only one which is not known since it contains the unknown deflection. The subsequent inversion of the matrix $[D]$ leads to, in effect, the solution to this differential equation and, in the beam analogy, corresponds to the integration of the loading to obtain the deflection. When numerical methods are used, the deflection may be computed with good accuracy by integration of the loading. On the other hand, if the difference equations which apply at an interior ordinate had been used, the matrix $[C]$ would have appeared as an operator on one of the known deflections on the right-hand side of the equation. Effectively, its operation would be to differentiate a known deflection, and in the beam analogy this operation corresponds to the attempt to obtain the load which caused a given deflection. This process, however, cannot be done with accuracy when numerical methods are used because of the difficulty encountered in the form of small differences of large numbers. The difference equations which apply at an outer ordinate and, consequently, lead to an integration process, therefore, have to be used.

DERIVATION OF THE INITIAL RESPONSE

As has been mentioned, some initial values of deflection are needed before equation (68) can be used. This section shows how these values are obtained. The airplane, just before gust penetration, is considered to be in level flight, and all displacements which follow are given relative to this level-flight condition. The initial conditions are that the vertical displacements, vertical velocity, wing rotation, and angular velocity are all zero. The gust force can be shown to start from zero and, therefore, by Newton's second law the additional initial condition can be established that the acceleration must be zero at the start of the response. These conditions can be satisfied, and the beginning of the response can be found by means of the analysis which follows.

The initial response is assumed to be given in terms of four successive ordinates, denoted by w_{-2}, w_{-1}, w_0 , and w_1 ; the w_0 ordinate is considered, as in the case of the damped oscillator, to locate the origin of time. The first and second derivatives at the w_0 ordinate are given by equations (8) and (9), respectively. By virtue of the initial conditions (the vanishing of the deflection, velocity, and accelerations at $t=0$), the ordinate w_0 and the derivatives given by equations (8) and (9) must be zero; therefore, the ordinates w_{-2} and w_{-1} are found to be related to the ordinate w_1 by the following relations:

$$w_{-2} = -8w_1 \quad (69)$$

$$w_{-1} = -w_1 \quad (70)$$

These relations are general and must apply for deflection and rotation at each of the spanwise stations and for the fuselage deflection as well; that is, the displacements at $t = -2\epsilon$ must be minus eight times the displacements at $t = \epsilon$, and the displacements at $t = -\epsilon$ must be the negative of those at $t = \epsilon$. Substituting these conditions in equation (64), taking n as equal to 1, and using the condition that the displacements are zero at $t=0$ give the following matrix equation in terms of the displacement at $t = \epsilon$ alone:

$$[D] + [S_2] + 8[S_3] \begin{vmatrix} \delta \\ w \\ \varphi \end{vmatrix}_1 = [R] \bar{L}_1 \quad (71)$$

The term $|\bar{F}|_1$ is zero and therefore does not appear in this equation. Solution of this equation gives the values of the displacements that occur at $t = \epsilon$ ($n=1$).

The three sets of initial displacements required to proceed with equation (68) are thus known: the set of deflections found at $t = \epsilon$, the zero set at $t = 0$, and the set at $t = -\epsilon$ given by equation (70), or simply the negative of the displacements which were found at $t = \epsilon$. In the actual case no displacements are present at $t = -\epsilon$, but these displacements may be regarded as being of a fictitious nature the only purpose of which is to allow the step-by-step evaluation of the displacements to be started easily:

DERIVATION OF GUST FORCES

The matrix $|\bar{L}_g|_n$ which appears in the response equation (68) is derived as follows. From equation (15) and the notation of equation (26), the total gust force acting over a station section at the n th time interval may be given by the equation

$$L_{g_n} = \beta c l \int_0^n \frac{\partial v}{\partial \tau} \psi(n\epsilon - \tau) d\tau \quad (72)$$

The integral in this expression is also of the Duhamel type and since the ψ function is expressed by exponential terms (see equations (21)), the integral may be evaluated quickly by a method similar to that developed in appendix D. The procedure of computing the gust force by this equation and then the response is not recommended, however, since a complete response evaluation would have to be made for each gust considered. Instead the procedure recommended is to compute the response due to a sharp-edge gust; then

with this response the response to any gust may be found directly by superposition.

Thus for the case of a sharp-edge gust, equation (72) reduces simply to

$$L_{g_n} = \beta c l v \psi_n \quad (73)$$

where ψ_n is the value of the ψ function at $t = n\epsilon$. This equation when applied to each of the spanwise stations leads directly to the matrix equation for gust force:

$$|L_g|_n = \beta \begin{vmatrix} c_0 l_0 v_0 \\ c_1 l_1 v_1 \\ c_2 l_2 v_2 \\ c_3 l_3 v_3 \\ c_4 l_4 v_4 \\ c_5 l_5 v_5 \end{vmatrix} \psi_n \quad (74)$$

If the gust is uniform in the spanwise direction, the v 's in this equation will all be equal.

In a similar manner, one-half the gust force acting on the tail due to a sharp-edge gust may be shown to be

$$L_{g_{t_n}} = \beta_{t_n} v_0 \psi_{t_n} \quad (75)$$

where the gust gradient is assumed to be the same as for station 0 and ψ_{t_n} is the value of the ψ function for the tail. This equation and equation (74) may now be combined to give the desired matrix $|\bar{L}_g|_n$ as follows:

$$|\bar{L}_g|_n = \begin{vmatrix} L_{g_t} \\ |L_g|_n \end{vmatrix} = \begin{vmatrix} \beta_{t_n} v_0 & 0 \\ 0 & \beta c_0 l_0 v_0 \\ 0 & \beta c_1 l_1 v_1 \\ 0 & \beta c_2 l_2 v_2 \\ 0 & \beta c_3 l_3 v_3 \\ 0 & \beta c_4 l_4 v_4 \\ 0 & \beta c_5 l_5 v_5 \end{vmatrix} \begin{vmatrix} \psi_t \\ \psi \end{vmatrix}_n \quad (76)$$

In the application of this equation it should be kept in mind that L_{g_t} does not begin to act until the tail starts to penetrate the gust. The time interval at which penetration starts may be taken as the interval nearest to the quantity $\frac{x_t}{\epsilon U}$.

COMPUTATION OF LOADS AND STRESSES

Once the time history of the displacements has been found from equation (68), the normal or torque loading on the wing can be found with little additional work. If the notation of equation (66) is used, equation (62) may be written

$$|P|_n = [S_0] \begin{vmatrix} \delta \\ w \\ \varphi \end{vmatrix}_n + |Q|_n \quad (77)$$

This equation shows that the loading matrix $|P|$ may be found by adding an easily computed matrix to the matrix $|Q|$, the value of which will have already been determined in the response calculation. The loading matrix $|P|$ is remembered

matrix $[\bar{F}]$ takes into account the forces which develop due to the "wake effect," and $[\bar{L}_g]$ is the gust-force matrix which is derived in step (3). Equation (78) is seen to give the displacements that occur at time n in terms of the displacements which occurred at the times $n-1$, $n-2$, and $n-3$.

The initial response:

(8) By use of the matrices given in step (6) and the gust forces which apply at $n=1$, set up the following matrix equation:

$$[[D] + [S_2] + 8[S_3]] \begin{bmatrix} \delta \\ w \\ \varphi_1 \end{bmatrix} = [R][\bar{L}_g]_1 \quad (79)$$

The term $[\bar{F}]_1$ does not appear in this equation because it is zero.

(9) Solve equation (79) for the displacements. Any convenient method, such as the Crout method (see reference 6), may be used. The displacements found will be the value of displacements that apply at $t=\epsilon$ or $n=1$.

The response:

(10) The response may now be found by successive application of equation (78). The response at $n=1$ has been found in step (9); the response at $n=2$ is next to be determined. The values of the displacements in the $n-2$ term of the response equation are all taken to be zero (initial condition), and the values in the $n-3$ term are taken as the negative of those found in step (9). The gust forces to use are those which apply at $n=2$. The deflections that apply at $n=2$ are then found by matrix algebra. For convenience the column matrix $[Q]$ is evaluated first, and then multiplication of this column matrix by the reciprocal of the $[D]$ matrix gives the deflections at $n=2$. With the newly found deflections at $n=2$ and the deflections at $n=1$ and $n=0$, the deflections at $n=3$ can be found, and so forth. This process is continued until the wing bending appears to be the most pronounced.

Wing loading:

(11) With the deflections known, the value of wing loading in bending or in torsion can be computed directly from equation (77). The stresses at any point can then be computed from the wing loading by ordinary static means. Since the loading may be computed at any value of time, the complete stress history of any point on the structure may be computed.

EXAMPLE

As an illustration of the method of analysis given in the present report, the response of a typical two-engine airplane due to a sharp-edge gust is determined. For brevity the fuselage is assumed rigid and only vertical displacement and wing bending are considered. The weight variation over the wing semispan and the equivalent-weight concentrations are shown in figure 8. In this figure are shown also the station locations and the interval covered by each station section. The solution is made for a forward velocity of flight of about 210 miles per hour and a gust velocity of 10 feet per second. In tables 2, 3, and 4 are listed, respectively, the various physical characteristics and the factors which

come from the unsteady lift function, the values of the ψ function and the gust-force matrix, and the matrix elements that are required for the solution (steps (1) to (5)). The Φ function for an aspect ratio of 6 was chosen (see equation (20b)); and the ψ function for an aspect ratio of infinity (equation (22)) was used.

The $[A]$ matrix as computed from the values of λ and I listed in table 4 is shown in table 5 (a). In the computation of the η values shown in table 4 for station 0, the fuselage was treated as a concentrated wing mass. This treatment is allowable since the fuselage is assumed rigid and further saves the work of computing the γ values (see equations (A8)). The $[[A]-[S_0]]$ or $[D]$ matrix, which in this case applies only to bending and vertical displacement, is shown in table 5 (b). The equation which is formed from equation (78) (step (7)) and which involves the reciprocal of $[D]$ and the $[S_i]$ and $[R]$ matrices is shown in table 6. The equation for computing the initial response (step (8)) is shown in table 7.

The solution to these equations is shown in figure 9 in which deflection in inches is plotted against spanwise station points for various intervals of time. For clarity the deflections for the odd intervals have been left off. From these curves the consequent wing bending and the manner in which the airplane is swept upward by the gust can be seen. The time histories of the loads (equation (77)) that occur at each of the spanwise stations are shown in figure 10. These curves indicate the presence of some second-mode excitation in the response. The stresses that occur at stations 0, 1, and 2 are shown in figure 11. The presence of second-mode excitation is not readily discernible from the stress curves.

DISCUSSION

A method for computing the stresses and structural action of an airplane flying through a gust has been given. The method is based on aerodynamic strip theory, but over-all corrections for compressibility and three-dimensional effects can be made as is indicated by a suggested correction procedure. Some tail forces are included in the analysis and others might equally well be included if their character is known.

The analysis as given is general enough to include the wing bending and twisting flexibilities and the fuselage flexibility. In a good many cases that may be considered, however, the last two of the flexibilities may prove to be of negligible importance. Some investigators have indicated (see reference 1) that, unless the forward speed of the airplane approaches the flutter or divergence speed of the wing, the torsional deformations do not have to be included. Likewise, in cases in which the fuselage is rather stiff, the effect of fuselage flexibility on the response may be rather small. In such cases in which either or both of these flexibilities may be ignored, the analysis is, of course, simplified and shortened. The example presented in the previous section illustrates this point. In the present state of understanding of gust-response analysis, enough information is not available to indicate definitely when and when not to include the various flexibilities of the aircraft structure. The analysis in the present report may provide a useful means to assess their importance. The extent, for example, to which coupling exists between wing bending and wing torsion in any particular case may be seen by comparing the displacements obtained from the coupling terms with the displacements obtained from the noncoupling terms.

Both the symmetrical and antisymmetrical types of gusts can be handled by the analysis given in the present report. In general, the symmetrical gust is expected to produce the most severe stress condition, and therefore only the matrices which apply for a symmetrical case have been given. These matrices were derived by using the boundary conditions for the symmetrical deformation of a free-free beam. The case of an antisymmetrical gust can be treated by replacing these matrices by the ones which apply for the antisymmetrical deformation of a free-free beam. The case of a general unsymmetrical gust can be handled by first breaking the gust into two parts—a symmetrical part and an antisymmetrical part—and then treating each part independently.

It might be of interest at this point to compare briefly the matrix method to a modal-function solution. One of the chief disadvantages of the modal-function solution is that the modes and frequencies of natural vibration of the structure have to be computed in advance. Then, a large number of integrals which involve these modes have to be determined in order to set up the problem. In the present analysis the physical properties of the airplane are used directly in the setting-up of the problem. Further, in order to make the

modal solution practical the higher modes must be dropped and only the basic or fundamental modes can be used. Hence, the success of the analysis depends to a large degree on how well single modal functions, one mode each for bending and torsion, can represent the airplane distortion. In the analysis of the present report the distortions are found for all practical purposes as the correct values at a number of spanwise stations, at least to within the accuracy to which the aerodynamic and structural parameters are known. Also, in this analysis, probably the most difficult operation is the inversion of the matrix $[D]$, which is actually not a very involved operation, especially when done by the quick and systematic procedure afforded by the Crout method (reference 6).

The present report indicates the methods for determining the response for both a sharp-edge gust and a gust of arbitrary shape. Probably the best approach, however, is to compute only the response for a sharp-edge gust, since the response for any arbitrary gust may thereafter be computed by means of Duhamel's integral. To follow such a procedure would also save a great amount of work in the evaluation of the gust forces.

One of the important features of the method of analysis presented is that it is not restricted to the gust problem. The approach used may be used to treat other problems of a similar nature. The landing problem can be handled by simply replacing the distributed gust force by the concentrated landing forces. In the landing problem also, the problem is set up much more easily since the aerodynamic terms do not ordinarily have to be included. However, the

landing problem in which aerodynamic forces are included may be solved by this method if desired. The approach used herein may also be used to solve the problem of the release of heavy objects such as bombs. This problem could be considered the inverse of the gust problem; a load is released rather than encountered. Some maneuvering problems, such as the sudden deflection of the ailerons, and a number of other transient problems might also be treated by an approach similar to that given in the present report.

CONCLUDING REMARKS

A method for computing the stresses and structural response of an aircraft flying through a gust has been presented. The method is based on aerodynamic strip theory, but compressibility and three-dimensional effects can be taken into account approximately by means of over-all corrections. The method takes into account wing bending and twisting deformations, fuselage deflection, vertical and pitching motion of the airplane, and some tail forces. A sharp-edge gust or a gust of arbitrary shape in the spanwise or flight directions may be treated. A suggested computational procedure is given to aid in the application of the method to any specific case.

The possibilities of applying the method to a variety of transient aircraft problems, such as landing, are brought out.

APPENDIX A

DEFINITIONS OF MATRICES USED IN ANALYSIS

For convenience in presentation, most of the matrices and matrix elements that are used in the analysis are defined in this appendix. The matrices are presented without derivations, but their origin should become evident by a study of the analysis.

Matrices.—The various matrices that are used in the analysis are defined as follows for the case in which the wing semispan is divided into six sections (the elements which are used in the matrices being defined in the subsequent section):

$$|w| = \begin{vmatrix} w(0) \\ w(1) \\ w(2) \\ w(3) \\ w(4) \\ w(5) \end{vmatrix}$$

$$|\varphi| = \begin{vmatrix} \varphi(1) \\ \varphi(2) \\ \varphi(3) \\ \varphi(4) \\ \varphi(5) \\ \varphi(6) \end{vmatrix}$$

$$\begin{vmatrix} \delta \\ w \\ \varphi \end{vmatrix} = \begin{vmatrix} \delta \\ |w| \\ |\varphi| \end{vmatrix}$$

$$|p| = \begin{vmatrix} p(0) \\ p(1) \\ p(2) \\ p(3) \\ p(4) \\ p(5) \end{vmatrix}$$

$$|q| = \begin{vmatrix} q(0) \\ q(1) \\ q(2) \\ q(3) \\ q(4) \\ q(5) \end{vmatrix}$$

$$|P| = \begin{vmatrix} 0 \\ |p| \\ |q| \end{vmatrix}$$

$$\begin{Bmatrix} [A] \\ [B] \end{Bmatrix} \left. \vphantom{\begin{Bmatrix} [A] \\ [B] \end{Bmatrix}} \right\} \text{See appendix C for definitions.}$$

$$[C] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & [A] & 0 \\ 0 & 0 & [B] \end{bmatrix}$$

$$[D] = [C] - [S_0]$$

$$[\eta_i] = \begin{bmatrix} \eta_i(0) + \gamma_i & & & & \\ & \eta_i(1) & & & \\ & & \eta_i(2) & & \\ & & & \eta_i(3) & \\ & & & & \eta_i(4) \\ & & & & & \eta_i(5) \end{bmatrix}$$

$$[\eta_i'] = \begin{bmatrix} \eta_i'(0) + \gamma_i' & & & & \\ & \eta_i'(1) & & & \\ & & \eta_i'(2) & & \\ & & & \eta_i'(3) & \\ & & & & \eta_i'(4) \\ & & & & & \eta_i'(5) \end{bmatrix}$$

$$[\nu_i] = \begin{bmatrix} \nu_i(0) + \mu_i & & & & \\ & \nu_i(1) & & & \\ & & \nu_i(2) & & \\ & & & \nu_i(3) & \\ & & & & \nu_i(4) \\ & & & & & \nu_i(5) \end{bmatrix}$$

$$[\nu_i'] = \begin{bmatrix} \nu_i'(0) + \mu_i' & & & & \\ & \nu_i'(1) & & & \\ & & \nu_i'(2) & & \\ & & & \nu_i'(3) & \\ & & & & \nu_i'(4) \\ & & & & & \nu_i'(5) \end{bmatrix}$$

$$|\bar{\gamma}_i| = \begin{bmatrix} \bar{\gamma}_i \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$|\bar{\mu}_i| = \begin{bmatrix} \bar{\mu}_i \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$[r_i] = [r_i \ 0 \ 0 \ 0 \ 0 \ 0]$$

$$[r'_i] = [r'_i \ 0 \ 0 \ 0 \ 0 \ 0]$$

$$[S_i] = \begin{bmatrix} \bar{r}_i & [r_i] & [r'_i] \\ |\bar{\gamma}_i| & [\eta_i] & [\eta'_i] \\ |\bar{\mu}_i| & [\nu_i] & [\nu'_i] \end{bmatrix}$$

$$|1| = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$|x_i| = \begin{bmatrix} -x_i \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$[I] = \begin{bmatrix} 1 & & & & & \\ & 1 & & & & \\ & & 1 & & & \\ & & & 1 & & \\ & & & & 1 & \\ & & & & & 1 \end{bmatrix}$$

$$\left[a - \frac{c}{4} \right] = \begin{bmatrix} \left(a - \frac{c}{4} \right)_0 & & & & & \\ & \left(a - \frac{c}{4} \right)_1 & & & & \\ & & \left(a - \frac{c}{4} \right)_2 & & & \\ & & & \left(a - \frac{c}{4} \right)_3 & & \\ & & & & \left(a - \frac{c}{4} \right)_4 & \\ & & & & & \left(a - \frac{c}{4} \right)_5 \end{bmatrix}$$

$$[R] = \begin{bmatrix} 1 & 0 \\ |1| & [I] \\ |x_i| & \left[a - \frac{c}{4} \right] \end{bmatrix}$$

$$[e] = \begin{bmatrix} e^{-\gamma_i \epsilon} & & & & & \\ & e^{-\gamma_i \epsilon} & & & & \\ & & e^{-\gamma_i \epsilon} & & & \\ & & & e^{-\gamma_i \epsilon} & & \\ & & & & e^{-\gamma_i \epsilon} & \\ & & & & & e^{-\gamma_i \epsilon} \end{bmatrix}$$

$$[j] = [j \ 0 \ 0 \ 0 \ 0 \ 0]$$

$$[j'] = [j' \ 0 \ 0 \ 0 \ 0 \ 0]$$

$$[g] = \begin{bmatrix} g(0) & & & & & \\ & g(1) & & & & \\ & & g(2) & & & \\ & & & g(3) & & \\ & & & & g(4) & \\ & & & & & g(5) \end{bmatrix}$$

$$[g'] = \begin{bmatrix} g'(0) & & & & & \\ & g'(1) & & & & \\ & & g'(2) & & & \\ & & & g'(3) & & \\ & & & & g'(4) & \\ & & & & & g'(5) \end{bmatrix}$$

$$[W] = \begin{bmatrix} \bar{j} & [j] & [j'] \\ 0 & [g] & [g'] \end{bmatrix}$$

Matrix elements.—The matrix elements which appear in the matrices defined in the previous section are expressed for convenience in terms of the following common factors:

$$\left. \begin{aligned} \beta &= m_A \pi \rho U & \Phi_0 &= a_1 \\ \gamma &= \frac{2U}{c_0} \lambda & \dot{\Phi}_0 &= -\gamma a_1 \\ & & \ddot{\Phi}_0 &= \gamma^2 a_1 \end{aligned} \right\} \quad (\text{A1})$$

in which the last four are associated with the Φ function for the wing. (See equation (23).) With these factors the elements that must be computed at each spanwise station are as follows:

$$\left. \begin{aligned} d_0 &= -\frac{11}{6\epsilon} (1-\Phi_0) \beta c l + \beta c l \left(\dot{\Phi}_0 + \frac{1}{2} \ddot{\Phi}_0 \epsilon \right) \\ d_1 &= \frac{3}{\epsilon} (1-\Phi_0) \beta c l \\ d_2 &= -\frac{3}{2\epsilon} (1-\Phi_0) \beta c l \\ d_3 &= \frac{1}{3\epsilon} (1-\Phi_0) \beta c l \\ d_0' &= \frac{11}{6\epsilon} (1-\Phi_0) \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) + \beta c l \left[U(1-\Phi_0) - \frac{1}{2} \dot{\Phi}_0 U \epsilon - \left(\dot{\Phi}_0 + \frac{1}{2} \ddot{\Phi}_0 \epsilon \right) c \left(\frac{3}{4} - \frac{a}{c} \right) \right] \\ d_1' &= -\frac{3}{\epsilon} (1-\Phi_0) \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) \\ d_2' &= \frac{3}{2\epsilon} (1-\Phi_0) \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) \\ d_3' &= -\frac{1}{3\epsilon} (1-\Phi_0) \beta c^2 l \left(\frac{3}{4} - \frac{a}{c} \right) \end{aligned} \right\} \quad (\text{A2})$$

$$\left. \begin{aligned} \eta_0 &= -\frac{2\overline{m}}{\epsilon^2} + d_0 & \eta_0' &= \frac{2\overline{m}\epsilon}{\epsilon^2} + d_0' + \frac{11}{24\epsilon} \beta c^2 l \\ \eta_1 &= \frac{5\overline{m}}{\epsilon^2} + d_1 & \eta_1' &= -\frac{5\overline{m}\epsilon}{\epsilon^2} + d_1' - \frac{3}{4\epsilon} \beta c^2 l \\ \eta_2 &= -\frac{4\overline{m}}{\epsilon^2} + d_2 & \eta_2' &= \frac{4\overline{m}\epsilon}{\epsilon^2} + d_2' + \frac{9}{24\epsilon} \beta c^2 l \\ \eta_3 &= \frac{\overline{m}}{\epsilon^2} + d_3 & \eta_3' &= -\frac{\overline{m}\epsilon}{\epsilon^2} + d_3' - \frac{1}{12\epsilon} \beta c^2 l \end{aligned} \right\} \quad (\text{A3})$$

$$\left. \begin{aligned} \nu_0 &= \frac{2\overline{m}\epsilon}{\epsilon^2} + d_0 \left(a - \frac{c}{4} \right) \\ \nu_1 &= -\frac{5\overline{m}\epsilon}{\epsilon^2} + d_1 \left(a - \frac{c}{4} \right) \\ \nu_2 &= \frac{4\overline{m}\epsilon}{\epsilon^2} + d_2 \left(a - \frac{c}{4} \right) \\ \nu_3 &= -\frac{\overline{m}\epsilon}{\epsilon^2} + d_3 \left(a - \frac{c}{4} \right) \\ \nu_0' &= -\frac{2\overline{m}\epsilon^2}{\epsilon^2} + d_0' \left(a - \frac{c}{4} \right) - \frac{11}{24\epsilon} \beta c^3 l \left(\frac{3}{4} - \frac{a}{c} \right) \\ \nu_1' &= \frac{5\overline{m}\epsilon^2}{\epsilon^2} + d_1' \left(a - \frac{c}{4} \right) + \frac{3}{4\epsilon} \beta c^3 l \left(\frac{3}{4} - \frac{a}{c} \right) \\ \nu_2' &= -\frac{4\overline{m}\epsilon^2}{\epsilon^2} + d_2' \left(a - \frac{c}{4} \right) + \frac{9}{24\epsilon} \beta c^3 l \left(\frac{3}{4} - \frac{a}{c} \right) \\ \nu_3' &= \frac{\overline{m}\epsilon^2}{\epsilon^2} + d_3' \left(a - \frac{c}{4} \right) + \frac{1}{12\epsilon} \beta c^3 l \left(\frac{3}{4} - \frac{a}{c} \right) \end{aligned} \right\} \quad (\text{A4})$$

$$\left. \begin{aligned} g &= \beta c l \ddot{\Phi}_0 \epsilon e^{-\gamma \epsilon} \\ g' &= \beta c l \epsilon e^{-\gamma \epsilon} \left[-U \dot{\Phi}_0 - \ddot{\Phi}_0 c \left(\frac{3}{4} - \frac{a}{c} \right) \right] \end{aligned} \right\} \quad (\text{A5})$$

The coefficients which must be computed for the fuselage and tail are expressed in part in terms of the following common factors:

$$\left. \begin{aligned} \beta_t &= \frac{1}{2} m_{A_t} \pi \rho U S_t & \Phi_{t_0} &= a_{1_t} \\ \gamma_t &= \frac{2U}{c_{0_t}} \lambda_t & \dot{\Phi}_{t_0} &= -\gamma_t a_{1_t} \\ & & \ddot{\Phi}_{t_0} &= \gamma_t^2 a_{1_t} \end{aligned} \right\} \quad (\text{A6})$$

in which the last four are associated with the Φ functions appropriate to the tail. Also used are the generalized masses given by equations (35) and the value θ_1 as given in equation (14). With these factors the coefficients for the tail and fuselage are as follows:

$$\left. \begin{aligned} f_0 &= -\frac{11}{6\epsilon} (1-\Phi_{t_0}) \beta_t + \beta_t \left(\dot{\Phi}_{t_0} + \frac{1}{2} \ddot{\Phi}_{t_0} \epsilon \right) \\ f_1 &= \frac{3}{\epsilon} (1-\Phi_{t_0}) \beta_t \\ f_2 &= -\frac{3}{2\epsilon} (1-\Phi_{t_0}) \beta_t \\ f_3 &= \frac{1}{3\epsilon} (1-\Phi_{t_0}) \beta_t \end{aligned} \right\} \quad (\text{A7a})$$

$$\left. \begin{aligned} f_0' &= \frac{11}{6\epsilon} (1 - \Phi_{t_0}) \left(x_t + \frac{1}{2} c_t \right) \beta_t + \beta_t \left[U(1 - \Phi_{t_0}) - \frac{1}{2} \dot{\Phi}_{t_0} U \epsilon - \left(\dot{\Phi}_{t_0} + \frac{1}{2} \ddot{\Phi}_{t_0} \epsilon \right) \left(x_t + \frac{1}{2} c_t \right) \right] + \frac{11}{24\epsilon} \beta_t c_t \\ f_1' &= -\frac{3}{\epsilon} (1 - \Phi_{t_0}) \left(x_t + \frac{1}{2} c_t \right) \beta_t - \frac{3}{4\epsilon} \beta_t c_t \\ f_2' &= \frac{3}{2\epsilon} (1 - \Phi_{t_0}) \left(x_t + \frac{1}{2} c_t \right) \beta_t + \frac{9}{24\epsilon} \beta_t c_t \\ f_3' &= -\frac{1}{3\epsilon} (1 - \Phi_{t_0}) \left(x_t + \frac{1}{2} c_t \right) \beta_t - \frac{1}{12\epsilon} \beta_t c_t \end{aligned} \right\} \quad (\text{A7b})$$

$$\left. \begin{aligned} \bar{f}_0 &= -\frac{11}{6\epsilon} (1 - \Phi_{t_0}) \left(1 + \frac{1}{2} c_t \theta_1 \right) \beta_t - \beta_t \left[U \theta_1 (1 - \Phi_{t_0}) - \frac{1}{2} \dot{\Phi}_{t_0} U \epsilon \theta_1 - \left(\dot{\Phi}_{t_0} + \frac{1}{2} \ddot{\Phi}_{t_0} \epsilon \right) \left(1 + \frac{1}{2} c_t \theta_1 \right) \right] - \frac{11}{24\epsilon} \beta_t c_t \theta_1 \\ \bar{f}_1 &= \frac{3}{\epsilon} (1 - \Phi_{t_0}) \left(1 + \frac{1}{2} c_t \theta_1 \right) \beta_t + \frac{3}{4\epsilon} \beta_t c_t \theta_1 \\ \bar{f}_2 &= -\frac{3}{2\epsilon} (1 - \Phi_{t_0}) \left(1 + \frac{1}{2} c_t \theta_1 \right) \beta_t - \frac{9}{24\epsilon} \beta_t c_t \theta_1 \\ \bar{f}_3 &= \frac{1}{3\epsilon} (1 - \Phi_{t_0}) \left(1 + \frac{1}{2} c_t \theta_1 \right) \beta_t + \frac{1}{12\epsilon} \beta_t c_t \theta_1 \end{aligned} \right\} \quad (\text{A7c})$$

$$\left. \begin{aligned} \gamma_0 &= -\frac{2M_1}{\epsilon^2} + f_0 \\ \gamma_1 &= \frac{5M_1}{\epsilon^2} + f_1 \\ \gamma_2 &= -\frac{4M_1}{\epsilon^2} + f_2 \\ \gamma_3 &= \frac{M_1}{\epsilon^2} + f_3 \end{aligned} \right\} \quad (\text{A8a})$$

$$\left. \begin{aligned} \gamma_0' &= \frac{2M_2}{\epsilon^2} + f_0' \\ \gamma_1' &= -\frac{5M_2}{\epsilon^2} + f_1' \\ \gamma_2' &= \frac{4M_2}{\epsilon^2} + f_2' \\ \gamma_3' &= -\frac{M_2}{\epsilon^2} + f_3' \end{aligned} \right\} \quad (\text{A8b})$$

$$\left. \begin{aligned} \bar{\gamma}_0 &= -\frac{2M_3}{\epsilon^2} + \bar{f}_0 \\ \bar{\gamma}_1 &= \frac{5M_3}{\epsilon^2} + \bar{f}_1 \\ \bar{\gamma}_2 &= -\frac{4M_3}{\epsilon^2} + \bar{f}_2 \\ \bar{\gamma}_3 &= \frac{M_3}{\epsilon^2} + \bar{f}_3 \end{aligned} \right\} \quad (\text{A8c})$$

$$\left. \begin{aligned} \mu_0 &= \frac{2M_2}{\epsilon^2} - x_i f_0 \\ \mu_1 &= -\frac{5M_2}{\epsilon^2} - x_i f_1 \\ \mu_2 &= \frac{4M_2}{\epsilon^2} - x_i f_2 \\ \mu_3 &= -\frac{M_2}{\epsilon^2} - x_i f_3 \end{aligned} \right\} \quad (\text{A9a})$$

$$\left. \begin{aligned} \mu_0' &= -\frac{2M_4}{\epsilon^2} - x_i f_0' \\ \mu_1' &= \frac{5M_4}{\epsilon^2} - x_i f_1' \\ \mu_2' &= -\frac{4M_4}{\epsilon^2} - x_i f_2' \\ \mu_3' &= \frac{M_4}{\epsilon^2} - x_i f_3' \end{aligned} \right\} \quad (\text{A9b})$$

$$\left. \begin{aligned} \bar{\mu}_0 &= \frac{2M_5}{\epsilon^2} - x_i \bar{f}_0 \\ \bar{\mu}_1 &= -\frac{5M_5}{\epsilon^2} - x_i \bar{f}_1 \\ \bar{\mu}_2 &= \frac{4M_5}{\epsilon^2} - x_i \bar{f}_2 \\ \bar{\mu}_3 &= -\frac{M_5}{\epsilon^2} - x_i \bar{f}_3 \end{aligned} \right\} \quad (\text{A9c})$$

$$\left. \begin{aligned} r_0 &= -\frac{2M_3}{\epsilon^2} + f_0 \\ r_1 &= \frac{5M_3}{\epsilon^2} + f_1 \\ r_2 &= -\frac{4M_3}{\epsilon^2} + f_2 \\ r_3 &= \frac{M_3}{\epsilon^2} + f_3 \end{aligned} \right\} \quad (\text{A10a})$$

$$\left. \begin{aligned} r_0' &= \frac{2M_5}{\epsilon^2} + f_0' \\ r_1' &= -\frac{5M_5}{\epsilon^2} + f_1' \\ r_2' &= \frac{4M_5}{\epsilon^2} + f_2' \\ r_3' &= -\frac{M_5}{\epsilon^2} + f_3' \end{aligned} \right\} \quad (\text{A10b})$$

$$\left. \begin{aligned} \bar{r}_0 &= -\frac{2M_6}{\epsilon^2} + \bar{f}_0 - \omega_f^2 M_6 \\ \bar{r}_1 &= \frac{5M_6}{\epsilon^2} + \bar{f}_1 \\ \bar{r}_2 &= -\frac{4M_6}{\epsilon^2} + \bar{f}_2 \\ \bar{r}_3 &= \frac{M_6}{\epsilon^2} + \bar{f}_3 \end{aligned} \right\} \quad (\text{A10c})$$

$$\left. \begin{aligned} j &= \beta_i \ddot{\Phi}_{t_0} \epsilon e^{-\gamma_i \epsilon} \\ j' &= \beta_i \epsilon e^{-\gamma_i \epsilon} \left[-U \dot{\Phi}_{t_0} - \ddot{\Phi}_{t_0} \left(x_i + \frac{1}{2} c_i \right) \right] \\ \bar{j} &= \beta_i \epsilon e^{-\gamma_i \epsilon} \left[U \dot{\Phi}_{t_0} \theta_1 + \ddot{\Phi}_{t_0} \left(1 + \frac{1}{2} c_i \theta_1 \right) \right] \end{aligned} \right\} \quad (\text{A11})$$

APPENDIX B

DERIVATION OF DIFFERENCE EQUATIONS

In this appendix the parabolic and cubic difference equations for the first and second derivatives of a function are derived.

Parabolic equations.—For the parabolic difference equation, consider the function shown in figure 12(a). This function is assumed to be replaced by the arc of a parabola which passes through the three ordinates a , b , and c . It can be verified readily that such a curve can be given by the equation

$$w = \frac{a}{2} \left(\frac{y}{\epsilon} - 1 \right) \left(\frac{y}{\epsilon} - 2 \right) - b \frac{y}{\epsilon} \left(\frac{y}{\epsilon} - 2 \right) + \frac{c}{2} \frac{y}{\epsilon} \left(\frac{y}{\epsilon} - 1 \right) \quad (\text{B1})$$

The first and second derivatives of this equation at $y = \epsilon$ are given by the equations

$$\left. \frac{dw}{dy} \right]_{y=\epsilon} = \frac{c-a}{2\epsilon} \quad (\text{B2})$$

$$\left. \frac{d^2w}{dy^2} \right]_{y=\epsilon} = \frac{c-2b+a}{\epsilon^2} \quad (\text{B3})$$

These equations are the standard difference equations for the first and second derivatives of a function. The derivatives are purposely taken at the middle of the three ordinates because the resulting equations are suitable for use in the simplification of many problems. If the derivative had been taken at an outer ordinate, the approximation afforded would not be accurate enough to be useful.

Cubic equations.—The cubic difference equations may be derived in a manner similar to that for the parabolic equations. In this case four successive ordinates are used. (See fig. 12(b).) The function is replaced by a third-degree curve which is given by the equation

$$w = -\frac{a}{6} \left(\frac{y}{\epsilon} - 1 \right) \left(\frac{y}{\epsilon} - 2 \right) \left(\frac{y}{\epsilon} - 3 \right) + \frac{b}{2} \frac{y}{\epsilon} \left(\frac{y}{\epsilon} - 2 \right) \left(\frac{y}{\epsilon} - 3 \right) - \frac{c}{2} \frac{y}{\epsilon} \left(\frac{y}{\epsilon} - 1 \right) \left(\frac{y}{\epsilon} - 3 \right) + \frac{d}{6} \frac{y}{\epsilon} \left(\frac{y}{\epsilon} - 1 \right) \left(\frac{y}{\epsilon} - 2 \right) \quad (\text{B4})$$

Because of the increase in accuracy that results from the use of a higher-degree curve, the first and second derivatives may be taken at an outer ordinate with an accuracy which is about equivalent to that given by equations (B2) and (B3). The derivatives at $y = 3\epsilon$ are

$$\left. \frac{dw}{dy} \right]_{y=3\epsilon} = \frac{11d-18c+9b-2a}{6\epsilon} \quad (\text{B5})$$

$$\left. \frac{d^2w}{dy^2} \right]_{y=3\epsilon} = \frac{2d-5c+4b-a}{\epsilon^2} \quad (\text{B6})$$

If taken at the third of the four ordinates, the derivatives are

$$\left. \frac{dw}{dy} \right]_{y=2\epsilon} = \frac{2d+3c-6b+a}{6\epsilon} \quad (\text{B7})$$

$$\left. \frac{d^2w}{dy^2} \right]_{y=2\epsilon} = \frac{d-2c+b}{\epsilon^2} \quad (\text{B8})$$

Equations (B5) and (B6) are used in the derivation of the response equation for an airplane in a gust. Equations (B7) and (B8) are useful in the derivation of the initial response.

(a) Parabolic.
(b) Cubic.

FIGURE 12.—Functional notation used in the derivation of parabolic and cubic difference equations.

APPENDIX C

DERIVATION OF MATRIX EQUATIONS OF EQUILIBRIUM

In this appendix the matrix equations

$$[A]|w| = |p| \quad (C1)$$

$$[B]|\varphi| = |q| \quad (C2)$$

for symmetrical bending and twisting of a free-free beam under normal and torsional loads are derived.

Bending.—In accordance with the assumptions made in this report the wing semispan is considered to be divided into six sections with a station point at the center of each section (see fig. 3). The inertia force of the mass and the aerodynamic force that develops over each section is in turn assumed to be concentrated at the respective station points. The wing is thus effectively a beam bending under six concentrated loads and, as such, will have a linearly varying moment between each station. The following general equation for the moment between the i and $i+1$ stations may therefore be written:

$$M = a_i + b_i y \quad (C3)$$

where

$$a_i = \left[1 + \frac{y(i)}{b\lambda_{i+1}} \right] M(i) - \frac{y(i)}{b\lambda_{i+1}} M(i+1)$$

$$b_i = \frac{1}{b\lambda_{i+1}} [M(i+1) - M(i)]$$

in which $y(i)$ is the abscissa to the i station.

The wing is further assumed to have a linear $1/EI$ variation between stations with the correct value of $1/EI$ at each station. This type of variation would lead to an EI curve which follows very closely the true stiffness curve of the wing and which of course has the correct values of EI at each station. A general equation for $1/EI$ may therefore also be written; thus,

$$\frac{1}{EI} = c_i + d_i y \quad (C4)$$

where

$$c_i = \left[1 + \frac{y(i)}{b\lambda_{i+1}} \right] \frac{1}{EI(i)} - \frac{y(i)}{b\lambda_{i+1}} \frac{1}{EI(i+1)}$$

$$d_i = \frac{1}{b\lambda_{i+1}} \left[\frac{1}{EI(i+1)} - \frac{1}{EI(i)} \right]$$

With equation (C3) and equation (C4) the well-known expression relating deflection to moment for a beam may be written

$$\frac{d^2 w}{dy^2} = \frac{M}{EI} = (a_i + b_i y)(c_i + d_i y) \quad (C5)$$

The deflection may be found most conveniently from this equation by use of the engineering beam theorem which states that the deflection of one point on a beam relative to the tangent of the deflection curve at another point is equal to the moment about the displaced point of the M/EI diagram between the two points. In this case symmetrical loading is being considered and therefore the boundary condition at the center line is that the slope must be zero; the deflection of each station relative to this point therefore may be readily computed. Fortunately, because of the convenient analytical representation of M/EI , these deflections may be found by exact integration. The deflection, for example, at station 4 due to the M/EI variation between stations i and $i+1$ may be given by the expression:

$$\int_{y(i)}^{y(i+1)} (a_i + b_i y)(c_i + d_i y)[y(4) - y] dy$$

Consideration of all the expressions of this sort leads to the total deflection of each station relative to the wing center line. From this deflection the more useful deflection relative to station 0 can be readily determined. The values of the deflection thus obtained are found to be expressible by the following matrix equation:

$$\begin{bmatrix} \bar{w}(1) \\ \bar{w}(2) \\ \bar{w}(3) \\ \bar{w}(4) \\ \bar{w}(5) \end{bmatrix} = \frac{b^2}{EI(0)} \begin{bmatrix} a_{11} & a_{12} & 0 & 0 & 0 \\ a_{21} & a_{22} & a_{23} & 0 & 0 \\ a_{31} & a_{32} & a_{33} & a_{34} & 0 \\ a_{41} & a_{42} & a_{43} & a_{44} & a_{45} \\ a_{51} & a_{52} & a_{53} & a_{54} & a_{55} \end{bmatrix} \begin{bmatrix} M(0) \\ M(1) \\ M(2) \\ M(3) \\ M(4) \end{bmatrix} \quad (C6)$$

where the matrix elements are defined by the equations:

$$\left. \begin{aligned} a_{11} &= \lambda_0 \lambda_1 + \lambda_1^2 A_1 \\ a_{21} &= \lambda_0(\lambda_1 + \lambda_2) + \lambda_1^2 A_1 + \lambda_1 \lambda_2 B_1 \\ a_{31} &= \lambda_0(\lambda_1 + \lambda_2 + \lambda_3) + \lambda_1^2 A_1 + \lambda_1(\lambda_2 + \lambda_3) B_1 \\ a_{41} &= \lambda_0(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4) + \lambda_1^2 A_1 + \lambda_1(\lambda_2 + \lambda_3 + \lambda_4) B_1 \\ a_{51} &= \lambda_0(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5) + \lambda_1^2 A_1 + \lambda_1(\lambda_2 + \lambda_3 + \lambda_4 + \lambda_5) B_1 \end{aligned} \right\} \quad (C7a)$$

$$\left. \begin{aligned} a_{12} &= \lambda_1^2 C_1 \\ a_{22} &= \lambda_1^2 C_1 + \lambda_1 \lambda_2 D_1 + \lambda_2^2 A_2 \\ a_{32} &= \lambda_1^2 C_1 + \lambda_1(\lambda_2 + \lambda_3) D_1 + \lambda_2^2 A_2 + \lambda_2 \lambda_3 B_2 \\ a_{42} &= \lambda_1^2 C_1 + \lambda_1(\lambda_2 + \lambda_3 + \lambda_4) D_1 + \lambda_2^2 A_2 + \lambda_2(\lambda_3 + \lambda_4) B_2 \\ a_{52} &= \lambda_1^2 C_1 + \lambda_1(\lambda_2 + \lambda_3 + \lambda_4 + \lambda_5) D_1 + \lambda_2^2 A_2 + \lambda_2(\lambda_3 + \lambda_4 + \lambda_5) B_2 \end{aligned} \right\} \quad (C7b)$$

$$\left. \begin{aligned} a_{23} &= \lambda_2^2 C_2 \\ a_{33} &= \lambda_2^2 C_2 + \lambda_2 \lambda_3 D_2 + \lambda_3^2 A_3 \\ a_{43} &= \lambda_2^2 C_2 + \lambda_2 (\lambda_3 + \lambda_4) D_2 + \lambda_3^2 A_3 + \lambda_3 \lambda_4 B_3 \\ a_{53} &= \lambda_2^2 C_2 + \lambda_2 (\lambda_3 + \lambda_4 + \lambda_5) D_2 + \lambda_3^2 A_3 + \lambda_3 (\lambda_4 + \lambda_5) B_3 \end{aligned} \right\} \quad (C7c)$$

$$\left. \begin{aligned} a_{34} &= \lambda_3^2 C_3 \\ a_{44} &= \lambda_3^2 C_3 + \lambda_3 \lambda_4 D_3 + \lambda_4^2 A_4 \\ a_{54} &= \lambda_3^2 C_3 + \lambda_3 (\lambda_4 + \lambda_5) D_3 + \lambda_4^2 A_4 + \lambda_4 \lambda_5 B_4 \end{aligned} \right\} \quad (C7d)$$

$$\left. \begin{aligned} a_{45} &= \lambda_4^2 C_4 \\ a_{55} &= \lambda_4^2 C_4 + \lambda_4 \lambda_5 D_4 + \lambda_5^2 A_5 \end{aligned} \right\} \quad (C7e)$$

in which

$$\left. \begin{aligned} A_i &= \frac{1}{4} \frac{I(0)}{I(i-1)} + \frac{1}{12} \frac{I(0)}{I(i)} \\ B_i &= \frac{1}{3} \frac{I(0)}{I(i-1)} + \frac{1}{6} \frac{I(0)}{I(i)} \\ C_i &= \frac{1}{12} \frac{I(0)}{I(i-1)} + \frac{1}{12} \frac{I(0)}{I(i)} \\ D_i &= \frac{1}{6} \frac{I(0)}{I(i-1)} + \frac{1}{3} \frac{I(0)}{I(i)} \end{aligned} \right\} \quad (C8)$$

The moment $M(5)$ does not appear in equation (C6) because the boundary condition is used so that the moment at station 5 is zero. For convenience equation (C6) may be given in the abbreviated form:

$$|\bar{w}| = \frac{b^2}{EI(0)} [H_1] |M| \quad (C9)$$

From the five loads $p(1)$, $p(2)$, $p(3)$, $p(4)$, and $p(5)$, the moment at each station may be found. The equations relating the moments to the loads can be shown to be given by the matrix equation:

$$\begin{bmatrix} M(0) \\ M(1) \\ M(2) \\ M(3) \\ M(4) \end{bmatrix} = b \begin{bmatrix} \lambda_1 & \lambda_1 + \lambda_2 & \lambda_1 + \lambda_2 + \lambda_3 & \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 & \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5 \\ 0 & \lambda_2 & \lambda_2 + \lambda_3 & \lambda_2 + \lambda_3 + \lambda_4 & \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5 \\ 0 & 0 & \lambda_3 & \lambda_3 + \lambda_4 & \lambda_3 + \lambda_4 + \lambda_5 \\ 0 & 0 & 0 & \lambda_4 & \lambda_4 + \lambda_5 \\ 0 & 0 & 0 & 0 & \lambda_5 \end{bmatrix} \begin{bmatrix} p(1) \\ p(2) \\ p(3) \\ p(4) \\ p(5) \end{bmatrix} \quad (C10)$$

which can be abbreviated simply

$$|M| = b [H_2] |p| \quad (C11)$$

Substitution of equation (C11) into equation (C9) gives

$$|\bar{w}| = \frac{b^3}{EI(0)} [H_1] [H_2] |p| \quad (C12)$$

Multiplication through by the reciprocal of $\frac{b^3}{EI(0)} [H_1] [H_2]$

results in the equation:

$$\frac{EI(0)}{b^3} [[H_1] [H_2]]^{-1} |\bar{w}| = |p| \quad (C13)$$

This equation thus gives the loads in terms of the deflection of each station relative to station 0. In the case under consideration, however, the wing is a free body capable of motion through space and therefore to set up properly the

equations of motion the deflection must be given relative to a fixed datum line. This datum line is most conveniently located as the position of the wing prior to action of the disturbing loads. Consideration of sketch 3

SKETCH 3.

will show therefore that the following relation must exist:

$$\bar{w} = w - w(0) \quad (C14)$$

Substitution of this equation into equation (C13) gives

$$\frac{EI(0)}{b^3} [[H_1][H_2]]^{-1} |w - w(0)| = |p| \quad (C15)$$

To aid in the derivation $\frac{EI(0)}{b^3} [[H_1][H_2]]^{-1}$ is now written in the general form:

$$\frac{EI(0)}{b^3} [[H_1][H_2]]^{-1} = \begin{bmatrix} b_{11} & b_{12} & b_{13} & b_{14} & b_{15} \\ b_{12} & b_{22} & b_{23} & b_{24} & b_{25} \\ b_{13} & b_{23} & b_{33} & b_{34} & b_{35} \\ b_{14} & b_{24} & b_{34} & b_{44} & b_{45} \\ b_{15} & b_{25} & b_{35} & b_{45} & b_{55} \end{bmatrix} \quad (C16)$$

Thus with this equation, equation (C15) may be transformed to the form:

$$\begin{bmatrix} b_{01} & b_{11} & b_{12} & b_{13} & b_{14} & b_{15} \\ b_{02} & b_{12} & b_{22} & b_{23} & b_{24} & b_{25} \\ b_{03} & b_{13} & b_{23} & b_{33} & b_{34} & b_{35} \\ b_{04} & b_{14} & b_{24} & b_{34} & b_{44} & b_{45} \\ b_{05} & b_{15} & b_{25} & b_{35} & b_{45} & b_{55} \end{bmatrix} \begin{bmatrix} w(0) \\ w(1) \\ w(2) \\ w(3) \\ w(4) \\ w(5) \end{bmatrix} = \begin{bmatrix} p(1) \\ p(2) \\ p(3) \\ p(4) \\ p(5) \end{bmatrix} \quad (C17)$$

where

$$\left. \begin{aligned} b_{01} &= -(b_{11} + b_{12} + b_{13} + b_{14} + b_{15}) \\ b_{02} &= -(b_{12} + b_{22} + b_{23} + b_{24} + b_{25}) \\ b_{03} &= -(b_{13} + b_{23} + b_{33} + b_{34} + b_{35}) \\ b_{04} &= -(b_{14} + b_{24} + b_{34} + b_{44} + b_{45}) \\ b_{05} &= -(b_{15} + b_{25} + b_{35} + b_{45} + b_{55}) \end{aligned} \right\} \quad (C18)$$

Equation (C17) is noted to express all the loads except $p(0)$ in terms of the six deflections. An additional equation in which $p(0)$ is expressed also in terms of the deflections may be established by use of the condition that all the loads acting on the wing semispan must add up to equal zero; that is,

$$p(0) + p(1) + p(2) + p(3) + p(4) + p(5) = 0 \quad (C19)$$

This condition automatically satisfies the two boundary conditions that the shear must be zero at the tip and center line of the wing. Thus if the five equations represented by equation (C17) are added, and use is made of equations (C18) and (C19), the following equation results:

$$b_{00}w(0) + b_{01}w(1) + b_{02}w(2) + b_{03}w(3) + b_{04}w(4) + b_{05}w(5) = p(0) \quad (C20)$$

where

$$b_{00} = -(b_{01} + b_{02} + b_{03} + b_{04} + b_{05}) \quad (C21)$$

This equation may now be combined with equation (C17) to give finally

$$\begin{bmatrix} b_{00} & b_{01} & b_{02} & b_{03} & b_{04} & b_{05} \\ b_{01} & b_{11} & b_{12} & b_{13} & b_{14} & b_{15} \\ b_{02} & b_{12} & b_{22} & b_{23} & b_{24} & b_{25} \\ b_{03} & b_{13} & b_{23} & b_{33} & b_{34} & b_{35} \\ b_{04} & b_{14} & b_{24} & b_{34} & b_{44} & b_{45} \\ b_{05} & b_{15} & b_{25} & b_{35} & b_{45} & b_{55} \end{bmatrix} \begin{bmatrix} w(0) \\ w(1) \\ w(2) \\ w(3) \\ w(4) \\ w(5) \end{bmatrix} = \begin{bmatrix} p(0) \\ p(1) \\ p(2) \\ p(3) \\ p(4) \\ p(5) \end{bmatrix} \quad (C22)$$

This equation is thus the desired matrix equation which relates the normal loads to the deflection. If the square matrix is denoted by $[A]$, the equation may be abbreviated conveniently to the form

$$[A] |w| = |p| \quad (C23)$$

which is the form used in the text. (See equation (40).)

As an aid in computational work, a summary of the steps involved in the determination of $[A]$ is given to close this section:

(1) From the I values at the respective stations, compute the coefficients given by equations (C8).

(2) With these coefficients determine the matrix elements given by equations (C7). These elements form the matrix $[H_1]$ which is defined by equations (C6) and (C9).

(3) Multiply the $[H_1]$ matrix by the $[H_2]$ matrix, which is defined by equations (C10) and (C11). The result should be a symmetrical matrix; this property serves as a very useful computational check.

(4) Invert the $\frac{b^3}{EI(0)} [[H_1][H_2]]$ matrix. This matrix should also be symmetrical. (The Crout method (reference 6) serves as a rather quick and useful means for performing the inversion.)

(5) Add the columns of the inverted matrix and place the negative of these sums at the top of their respective columns such as to form a new row of matrix elements. Then add these sums and place the negative of the sum as the first matrix element of the newly formed row. A new column headed by this value is thus in the making. Fill in the remainder of the column with the respective elements of the new row; that is, the appropriate values should be inserted to make the matrix symmetrical. This final matrix is the desired [A] matrix.

Torsion.—For the torsional case the torque loads q are assumed to be concentrated at the stations just as in the case for the normal loads p . Consideration then of the following example torque diagram (sketch 4)

will show that the following equations must apply:

$$\left. \begin{aligned} q(0) &= -T(1) \\ q(1) &= T(1) - T(2) \\ q(2) &= T(2) - T(3) \\ q(3) &= T(3) - T(4) \\ q(4) &= T(4) - T(5) \\ q(5) &= T(5) \end{aligned} \right\} \quad (C24)$$

where $T(i)$ represents the total torque present in the i interval. No torque exists between the wing center line and station 0.

To aid in the derivation, the assumption is made that $1/GJ$ varies linearly between stations. A typical T/GJ diagram between, say, the $i-1$ and the i stations would appear as in sketch 5:

From the differential relation $\frac{d\varphi}{dy} = \frac{T}{GJ}$, the fact may be observed that the change in angle of twist between two stations is equal to the area of the T/GJ diagram between the two stations; therefore,

$$\varphi(i) - \varphi(i-1) = \frac{b\lambda_i}{2} \left[\frac{T(i)}{GJ(i-1)} + \frac{T(i)}{GJ(i)} \right] \quad (C25)$$

If the notation

$$j_i = \frac{2G}{b\lambda_i} \frac{1}{\frac{1}{J(i-1)} + \frac{1}{J(i)}} \quad (C26)$$

is employed, equation (C25) may be written

$$T(i) = j_i [\varphi(i) - \varphi(i-1)] \quad (C27)$$

Application of this equation to each of the spanwise stations gives the following equations for T :

$$\left. \begin{aligned} T(1) &= j_1 [\varphi(1) - \varphi(0)] \\ T(2) &= j_2 [\varphi(2) - \varphi(1)] \\ T(3) &= j_3 [\varphi(3) - \varphi(2)] \\ T(4) &= j_4 [\varphi(4) - \varphi(3)] \\ T(5) &= j_5 [\varphi(5) - \varphi(4)] \end{aligned} \right\} \quad (C28)$$

Substitution now of these equations into equations (C24) gives the desired equations relating the torque loads to the angle of twist. The equations thus found can be given in the matrix form:

$$\begin{bmatrix} j_1 & -j_1 & 0 & 0 & 0 & 0 \\ -j_1 & (j_1 + j_2) & -j_2 & 0 & 0 & 0 \\ 0 & -j_2 & (j_2 + j_3) & -j_3 & 0 & 0 \\ 0 & 0 & -j_3 & (j_3 + j_4) & -j_4 & 0 \\ 0 & 0 & 0 & -j_4 & (j_4 + j_5) & -j_5 \\ 0 & 0 & 0 & 0 & -j_5 & j_5 \end{bmatrix} \begin{bmatrix} \varphi(0) \\ \varphi(1) \\ \varphi(2) \\ \varphi(3) \\ \varphi(4) \\ \varphi(5) \end{bmatrix} = \begin{bmatrix} q(0) \\ q(1) \\ q(2) \\ q(3) \\ q(4) \\ q(5) \end{bmatrix} \quad (C29)$$

which can be abbreviated to

$$[B] |\varphi| = |q| \quad (C30)$$

the form used in the test. (See equation (41).) Thus all that is involved in the computation of the matrix [B] is the evaluation of the matrix elements by means of equation (C26).

APPENDIX D

RECURRENCE EQUATION FOR THE EVALUATION OF DUHAMEL'S INTEGRAL INVOLVING AN EXPONENTIAL KERNEL

The derivation of a rather simple recurrence relation for the step-by-step evaluation of the three unsteady lift integrals appearing in equation (25) is presented. This derivation is made possible because the kernels of the integrals are expressible in exponential form.

From equation (23) the first and second derivatives of the Φ function may be written

$$\dot{\Phi} = -\frac{2U}{c_0} \lambda a_1 e^{-\lambda \frac{2U}{c_0} t} = \dot{\Phi}_0 e^{-\gamma t} \quad (D1)$$

$$\ddot{\Phi} = \frac{4U^2}{c_0^2} \lambda^2 a_1 e^{-\lambda \frac{2U}{c_0} t} = \ddot{\Phi}_0 e^{-\gamma t} \quad (D2)$$

where

$$\gamma = \lambda \frac{2U}{c_0}$$

$$\dot{\Phi}_0 = -\gamma a_1$$

$$\ddot{\Phi}_0 = \gamma^2 a_1$$

With these equations the three integrals of equation (25) may be combined conveniently into the following single integral denoted by I_t :

$$I_t = \int_0^t \left\{ \ddot{\Phi}_0 \beta c l w - \left[\dot{\Phi}_0 \beta c l U + \ddot{\Phi}_0 \beta c l \left(\frac{3}{4} - \frac{a}{c} \right) \right] \varphi \right\} e^{-\gamma(t-\tau)} d\tau \quad (D3)$$

For convenience the notation

$$Y = \left\{ \ddot{\Phi}_0 \beta c l w - \left[\dot{\Phi}_0 \beta c l U + \ddot{\Phi}_0 \beta c l \left(\frac{3}{4} - \frac{a}{c} \right) \right] \varphi \right\} \quad (D4)$$

is introduced and thus equation (D3) becomes

$$I_t = \int_0^t Y e^{-\gamma(t-\tau)} d\tau$$

or

$$I_t = e^{-\gamma t} \int_0^t Y e^{\gamma \tau} d\tau \quad (D5)$$

Mathematically, the integral in this equation may be interpreted to represent the area under the function given as a product of Y and $e^{\gamma \tau}$. In accordance with numerical evaluation processes, the interval 0 to t may be divided into a number of time stations of interval ϵ . The product of Y and $e^{\gamma \tau}$ may then be found at each of the time stations and from these products the area under the curve may be determined in first approximation by the trapezoidal method of determining areas. Thus, if the time station n corresponds to time t , the expression for I_t may be approximated as follows:

$$I_t \approx I_n = \epsilon e^{-\gamma n \epsilon} \left[Y_1 e^{\gamma \epsilon} + Y_2 e^{\gamma 2 \epsilon} + \dots + Y_{n-1} e^{\gamma(n-1)\epsilon} + \frac{1}{2} Y_n e^{\gamma n \epsilon} \right] \quad (D6)$$

where Y_0 does not appear since the initial conditions are used that the deflection w and rotation φ are zero at $t=0$, and therefore Y_0 is zero. (See equation (D4).) More accurate methods, such as Simpson's method, could be used for determining the area under the curve, but because of the small interval chosen the consequent increase in accuracy is negligible. If the notation

$$F_n = \epsilon e^{-\gamma n \epsilon} [Y_1 e^{\gamma \epsilon} + Y_2 e^{\gamma 2 \epsilon} + \dots + Y_{n-1} e^{\gamma(n-1)\epsilon}] \quad (D7)$$

is introduced, equation (D6) may be written simply

$$I_n = F_n + \frac{\epsilon}{2} Y_n \quad (D8)$$

If equation (D5) is expanded similarly, only for an upper limit of $t - \epsilon$, the expanded result would be

$$I_{n-1} = \epsilon e^{-\gamma(n-1)\epsilon} \left[Y_1 e^{\gamma \epsilon} + Y_2 e^{\gamma 2 \epsilon} + \dots + Y_{n-2} e^{\gamma(n-2)\epsilon} + \frac{1}{2} Y_{n-1} e^{\gamma(n-1)\epsilon} \right] \quad (D9)$$

By analogy with equation (D7), however,

$$F_{n-1} = \epsilon e^{-\gamma(n-1)\epsilon} [Y_1 e^{\gamma \epsilon} + Y_2 e^{\gamma 2 \epsilon} + \dots + Y_{n-2} e^{\gamma(n-2)\epsilon}] \quad (D10)$$

and therefore equation (D9) becomes

$$I_{n-1} = F_{n-1} + \frac{\epsilon}{2} Y_{n-1} \quad (D11)$$

A study of equations (D7) and (D10) shows that the following relation must exist:

$$F_n = e^{-\gamma \epsilon} F_{n-1} + \epsilon e^{-\gamma \epsilon} Y_{n-1} \quad (D12)$$

Now, if equation (D4) is used to rewrite Y_n and Y_{n-1} in equations (D8) and (D12), the value of I_n may be given finally by the equation:

$$I_n = F_n + \frac{1}{2} \ddot{\Phi}_0 \beta c l \epsilon w_n - \frac{1}{2} \beta c l \epsilon \left[U \dot{\Phi}_0 + c \left(\frac{3}{4} - \frac{a}{c} \right) \ddot{\Phi}_0 \right] \varphi_n \quad (D13)$$

where

$$F_n = e^{-\gamma \epsilon} F_{n-1} + \ddot{\Phi}_0 \epsilon e^{-\gamma \epsilon} \beta c l w_{n-1} - \beta c l \epsilon e^{-\gamma \epsilon} \left[U \dot{\Phi}_0 + c \left(\frac{3}{4} - \frac{a}{c} \right) \ddot{\Phi}_0 \right] \varphi_{n-1} \quad (D14)$$

The value of the unsteady lift integrals is thus given by equation (D13). As regards the analysis given in the present report, w_{n-1} and φ_{n-1} are the values of deflection and rotation which have, say, just been determined from the recurrence equation for response. The value F_{n-1} was also established and therefore F_n can be determined as a definite quantity. The value I_n is thus seen to be given in terms of the known F_n and in terms of w_n and φ_n which are the next values to be evaluated from the recurrence equation.

APPENDIX E

MATRIX ALGEBRA.

This appendix is written for those not familiar with matrix notations or matrix methods. All the matrix algebra necessary for the understanding of this report is described hereinafter by way of examples.

Matrix definition.—Some of the basic types of matrices are illustrated by the following arbitrary matrices which are of the third order:

The column matrix

$$\begin{bmatrix} 2 \\ 1 \\ -1 \end{bmatrix}$$

The row matrix

$$\begin{bmatrix} 2 & -3 & 1 \end{bmatrix}$$

The square matrix

$$\begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix}$$

The diagonal matrix

$$\begin{bmatrix} 4 & 0 & 0 \\ 0 & 3 & 0 \\ 0 & 0 & -1 \end{bmatrix}$$

The identity matrix

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

Element definition.—Each of the terms that appear in a matrix is defined as an element. Its position is usually denoted in a row by the number of terms from the left and in a column by the number of terms from the top.

Matrix addition.—The addition of two matrices produces a single matrix. Addition is performed by simply adding together corresponding elements. For example,

$$\begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix} + \begin{bmatrix} 4 & -1 & 0 \\ 0 & 3 & 2 \\ 2 & 0 & -1 \end{bmatrix} = \begin{bmatrix} 6 & -4 & 1 \\ 1 & 5 & 0 \\ 1 & -1 & 2 \end{bmatrix}$$

Multiplication of a matrix by a scalar number.—In the multiplication of a matrix by a scalar number every element in the matrix is multiplied by the number. For example,

$$2 \begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix} = \begin{bmatrix} 4 & -6 & 2 \\ 2 & 4 & -4 \\ -2 & -2 & 6 \end{bmatrix}$$

Multiplication of a column matrix by a row matrix.—The product of a column matrix and a row matrix is equal to the sum of the products of the corresponding elements. For example,

$$\begin{bmatrix} 2 & -3 & 1 \end{bmatrix} \begin{bmatrix} 2 \\ 1 \\ -4 \end{bmatrix} = (2 \times 2) + (-3 \times 1) + [1 \times (-4)] = -3$$

Multiplication of a column matrix by a square matrix.—The multiplication of a column matrix by a square matrix produces a column matrix. Consider the following set of three simultaneous equations:

$$\left. \begin{aligned} 2y_1 - 3y_2 + y_3 &= a_1 \\ y_1 + 2y_2 - 2y_3 &= a_2 \\ -y_1 - y_2 + 3y_3 &= a_3 \end{aligned} \right\} \quad (\text{E1})$$

The procedure adopted in matrix algebra is to write these equations in the matrix form

$$\begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} \quad (\text{E2})$$

where the multiplication of the $|y|$ column matrix by each row in the square matrix produces the respective elements in the $|a|$ column matrix. (See multiplication of a column matrix by a row matrix.)

In order to simplify the presentation of an analysis, the symbolic or abbreviated matrix form is used quite often. The symbolic form of equation (E2) is simply

$$[M] |y| = |a| \quad (\text{E3})$$

The determination of $|a|$ by the multiplication of $|y|$ by $[M]$ is illustrated with arbitrary values of y , say $y_1=4$, $y_2=5$, and $y_3=6$, by the following equation:

$$\begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix} \begin{bmatrix} 4 \\ 5 \\ 6 \end{bmatrix} = \begin{bmatrix} (2 \times 4) + (-3 \times 5) + (1 \times 6) \\ (1 \times 4) + (2 \times 5) + (-2 \times 6) \\ (-1 \times 4) + (-1 \times 5) + (3 \times 6) \end{bmatrix} = \begin{bmatrix} -1 \\ 2 \\ 9 \end{bmatrix} = \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} \quad (\text{E4})$$

Multiplication of a square matrix by a square matrix.—The multiplication of two square matrices produces a square matrix. Multiplication is performed by letting the multiplying matrix operate, as in the preceding section, on each of the successive columns in the matrix being multiplied to produce corresponding successive columns in the product matrix. For example,

$$\begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix} \begin{bmatrix} 1 & -2 & 3 \\ 1 & 3 & -2 \\ -1 & 1 & 2 \end{bmatrix} = \begin{bmatrix} -2 & -12 & 14 \\ 5 & 2 & -5 \\ -5 & 2 & 5 \end{bmatrix} \quad (\text{E5})$$

Order of multiplication.—In general the commutative multiplication law of ordinary algebra does not hold in matrix methods; that is,

$$|A| |B| \neq |B| |A|$$

Therefore, whenever the product of several matrices is indicated, these matrices must be multiplied together without changing their order.

Matrix partitioning and submatrices.—A matrix may be partitioned or divided at will into smaller matrices. For example, the left-hand side of equation (E4) may be partitioned as follows:

$$\left[\begin{array}{c|cc} 2 & -3 & 1 \\ \hline - & - & - \\ 1 & 2 & -2 \\ \hline -1 & -1 & 3 \end{array} \right] \left| \begin{array}{c} 4 \\ 5 \\ 6 \end{array} \right|$$

The matrices which are formed by the dividing lines are called submatrices. These submatrices may be treated as though they were elements when matrix operations are performed. For example, with the notation

$$\begin{aligned} a &= \begin{bmatrix} -3 & 1 \end{bmatrix} \\ b &= \begin{bmatrix} 1 \\ -1 \end{bmatrix} \\ c &= \begin{bmatrix} 2 & -2 \\ -1 & 3 \end{bmatrix} \\ d &= \begin{bmatrix} 5 \\ 6 \end{bmatrix} \end{aligned}$$

the multiplication of the foregoing partitioned matrix is as follows:

$$\left[\begin{array}{c|c} 2 & a \\ \hline - & - \\ b & c \end{array} \right] \left| \begin{array}{c} 4 \\ d \end{array} \right| = \left| \begin{array}{c} 8+ad \\ 4b+cd \end{array} \right|$$

The reciprocal of a matrix and the identity matrix.—By ordinary algebraic methods the formal operation involved in the solution for x of the equation

$$mx = a$$

is the multiplication through by the reciprocal of m ; thus,

$$x = m^{-1}a$$

The same formal operation may be applied to matrix equations. For example, the solution for $|y|$ in equation (E3) is simply

$$|y| = [M]^{-1}|a|$$

where $[M]^{-1}$ is the reciprocal, or the inverse, of $[M]$.

The reciprocal of a matrix is found as the matrix which satisfies either of the equivalent equations

$$[M]^{-1} [M] = [I]$$

$$[M] [M]^{-1} = [I]$$

where $[I]$ is the identity matrix. For equations (E2) and (E3), the reciprocal of $[M]$ is found as the matrix which satisfies the equation

$$\begin{bmatrix} 2 & -3 & 1 \\ 1 & 2 & -2 \\ -1 & -1 & 3 \end{bmatrix} \begin{bmatrix} b_1 & c_1 & d_1 \\ b_2 & c_2 & d_2 \\ b_3 & c_3 & d_3 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

If this equation is considered in relation to equations (E1), (E2), and (E5), the values of b_1 , b_2 , and b_3 would simply be values of y_1 , y_2 , and y_3 which satisfy equation (E1) for $a_1=1$, $a_2=0$, and $a_3=0$; c_1 , c_2 , and c_3 would be the values for $a_1=0$, $a_2=1$, and $a_3=0$; and d_1 , d_2 , and d_3 would be the values for $a_1=0$, $a_2=0$, and $a_3=1$. For this example, the solutions are

$$b_1 = \frac{1}{3} \quad c_1 = \frac{2}{3} \quad d_1 = \frac{1}{3}$$

$$b_2 = -\frac{1}{12} \quad c_2 = \frac{7}{12} \quad d_2 = \frac{5}{12}$$

$$b_3 = \frac{1}{12} \quad c_3 = \frac{5}{12} \quad d_3 = \frac{7}{12}$$

The Crout method (reference 6) provides a very quick and convenient method for determining these solutions.

The determination of y by the operation $[M]^{-1}$ on $|a|$ is illustrated as follows for $a_1 = -1$, $a_2 = 2$, and $a_3 = 9$:

$$\frac{1}{12} \begin{bmatrix} 4 & 8 & 4 \\ -1 & 7 & 5 \\ 1 & 5 & 7 \end{bmatrix} \left| \begin{array}{c} -1 \\ 2 \\ 9 \end{array} \right| = \left| \begin{array}{c} 4 \\ 5 \\ 6 \end{array} \right| \quad (\text{E11})$$

The operation performed by this equation can be seen to be the inverse operation of equation (E4).

REPORT 1011

DYNAMICS OF A TURBOJET ENGINE CONSIDERED AS A QUASI-STATIC SYSTEM¹

By EDWARD W. OTTO and BURT L. TAYLOR, III¹

SUMMARY

A determination of the dynamic characteristics of a typical turbojet engine with a centrifugal compressor, a sonic-flow turbine-nozzle diaphragm, and fixed-area exhaust nozzle is presented. A generalized equation for the transient behavior of the engine was developed; this equation was then verified by calculations using compressor- and turbine-performance charts extrapolated from equilibrium operating data and by experimental data obtained from an engine operated under transients in fuel flow.

The results indicate that a linear differential equation for engine acceleration as a function of fuel flow and engine speed for operation near a steady-state operating condition can be written. The coefficients of this equation can be obtained either from actual transient data or with a fair degree of accuracy from the steady-state performance maps of the compressor and turbine and can be corrected for altitude in the same manner that steady-state performance data are corrected.

INTRODUCTION

In a turbojet engine, the various engine variables such as speed and thrust respond comparatively slowly to changes in fuel flow—much more slowly than reciprocating-engine variables such as torque respond to changes in manifold pressure. Any control mechanism charged with the responsibility of keeping turbojet-engine variables at a set value is faced with the problem of changing the fuel flow in response to errors in the controlled variable at a rate that is fast enough to bring the variable back to the set value as quickly as possible but not so fast that excessive turbine temperatures are encountered. The same problem is encountered when the control is asked to change the speed or thrust from one set value to another. Thus, to insure the design of a successful control the designer must have information regarding the response rate of the particular engine variable that he is interested in controlling.

A study of the dynamic behavior of engine speed, made at the NACA Lewis laboratory in 1948, is presented herein.

This variable rather than thrust has been studied because, in the turbojet engine, speed is almost analogous to thrust and can be more easily and more accurately measured. Obviously, other engine variables may possess as many advantages for use as a thrust-control parameter. A previous investigation at this laboratory has indicated, however, that speed is the best parameter available because no other engine variable exhibits as many advantages as does speed. At the present time speed is used almost universally as a thrust-control parameter in turbojet engines.

It was felt that the needs of the control designer would be best served if the dynamic behavior of engine speed could be expressed in mathematical form and if altitude corrections to this expression could be indicated. Also it is desirable to know whether or not the engine dynamics can be predicted within reason from the steady-state performance charts of the engine components. Accordingly, the study contained herein was pursued as follows: A differential equation relating speed and fuel flow was derived by considering the thermodynamic and flow processes to be quasi-static. Altitude corrections were then applied to this equation in the same manner as steady-state altitude corrections are applied. The coefficients of the terms of the differential equation were obtained by plotting accelerating torque as a function of fuel flow and speed from calculations involving the use of the steady-state performance charts of the engine components. A typical engine was then operated under certain transients of fuel flow to obtain experimental data for a verification of both the differential equation derived and the coefficients obtained from steady-state component data.

ANALYSIS

In a turbojet engine of the type under consideration, an increase in fuel flow at constant speed causes an increase in turbine-inlet temperature, which results in an increase in turbine torque. The difference between the turbine torque and the torque absorbed by the compressor then accelerates the engine according to the following equation:

$$\alpha = \frac{Q}{I}$$

¹ Supersedes NACA TN 2091, "Dynamics of Turbojet Engine Considered as Quasi-Static System" by Edward W. Otto and Burt L. Taylor, III, 1950.

FIGURE 1.—Typical configuration of turbojet engine.

where α is the angular acceleration, Q is the difference between the instantaneous torque output of the turbine and the instantaneous torque absorbed by the compressor, and I is the polar moment of inertia of all rotating parts. Thus the effect of a change in fuel flow on engine acceleration is proportional to the effect of a change in fuel flow on the difference between torque output of the turbine and torque absorbed by the compressor. From a general consideration of the mechanics of the system, therefore, a differential equation relating speed and fuel flow can be written. This equation can then be correlated with data from a typical engine of the type under consideration. This procedure is demonstrated with an engine consisting of the components shown in figure 1.

DEVELOPMENT OF GENERALIZED ENGINE EQUATION

For the equilibrium running conditions of turbojet engines, various engine parameters may be represented by general functional forms of the one independent variable, effective fuel flow; that is, $N=f(W_f\eta_b)$, $T_4=g(W_f\eta_b)$, and so forth. (All symbols are defined in appendix A.) The development of general functional forms relating the variables during transient conditions of operation requires some hypothesis concerning the thermodynamic and flow processes during these periods. The hypothesis made herein is that the processes are quasi-static; that is, they act like a continuous series of equilibrium states. Each point of the dynamic state is an equilibrium condition for the flow and thermodynamic processes. It follows that a point reached by each component of the system during the transient corresponds to some equilibrium point for that component. Furthermore, the point encountered by the complete engine, being a sum of the components, is also some equilibrium point for the complete engine.

Without altering the turbojet-engine geometry, equilibrium operating points other than the equilibrium operating conditions can be obtained only by applying an outside

load to the engine. The action of an external load creates an additional independent variable for the dynamic state. This action may be expressed in terms of some engine variable, which allows this variable to be considered as the additional independent variable. For transient conditions of operation, various dependent variables of the engine may therefore be considered as functions of the effective fuel flow and another engine variable.

Because this analysis is concerned with the transient behavior of engine speed, this variable was chosen as the additional independent variable for the dynamic state. Unbalanced torque was chosen as the dependent variable because of its relation to engine speed. The assumed functional relation is therefore:

$$Q=f(W_f\eta_b, N) \quad (1)$$

This function may be expanded about an initial point i as follows:

$$\begin{aligned} Q=f(W_f\eta_b, N) &= Q_i + \left[\frac{\partial Q}{\partial (W_f\eta_b)} \right]_i [W_f\eta_b - (W_f\eta_b)_i] + \\ &\quad \left(\frac{\partial Q}{\partial N} \right)_i (N - N_i) + \frac{\left[\frac{\partial^2 Q}{\partial (W_f\eta_b)^2} \right]_i [W_f\eta_b - (W_f\eta_b)_i]^2}{2!} + \\ &\quad \frac{2 \left[\frac{\partial^2 Q}{\partial (W_f\eta_b) \partial N} \right]_i [W_f\eta_b - (W_f\eta_b)_i] (N - N_i)}{2!} + \\ &\quad \frac{\left(\frac{\partial^2 Q}{\partial N^2} \right)_i (N - N_i)^2}{2!} + \dots \end{aligned} \quad (2)$$

When the deviation from the point i is sufficiently small, the terms containing products of higher derivatives and products or powers of small numbers become negligible and only the

first three terms of equation (2) are of significant value. Furthermore, if the point i is a steady-state point o , the initial value of accelerating torque Q_i is zero.

When the deviations from the steady state are denoted by Δ , the significant terms of equation (2) can be written as

$$Q = \left[\frac{\partial Q}{\partial (W_f \eta_b)} \right]_o \Delta(W_f \eta_b) + \left(\frac{\partial Q}{\partial N} \right)_o \Delta N \quad (3)$$

The accelerating torque can also be expressed as a function of engine acceleration as

$$Q = \frac{I d(N - N_o)}{dt} = I \frac{d(\Delta N)}{dt} \quad (4)$$

Substitution of equation (4) in equation (3) and rearrangement give

$$I \frac{d(\Delta N)}{dt} = \left[\frac{\partial Q}{\partial (W_f \eta_b)} \right]_o \Delta(W_f \eta_b) + \left(\frac{\partial Q}{\partial N} \right)_o \Delta N \quad (5)$$

Equation (5) represents the dynamic behavior of engine speed in that it gives engine acceleration as a function of fuel flow and speed.

A graphical representation of equation (5) for given altitude and ram conditions is shown in figure 2 (a). The $Q=0$ line is the steady-state operating line. The slope of any constant-speed line of figure 2(a) at $Q=0$ is $\left[\frac{\partial Q}{\partial (W_f \eta_b)} \right]_o$ and the slope of any constant-fuel-flow line of figure 2 (a) at $Q=0$ is $\left(\frac{\partial Q}{\partial N} \right)_o$. Equation (5) can therefore be rewritten as

$$I \frac{d(\Delta N)}{dt} = a_o \Delta(W_f \eta_b) - b_o \Delta N \quad (6)$$

where a_o is the numerical value of the slope of the torque-

fuel-flow curves at constant speed and b_o is the numerical value of the slope of the torque-speed curves at constant fuel flow.

Equation (6) holds only for constant altitude and ram conditions. Because speed, fuel-flow, and torque can all be corrected for altitude, however, equation (6) can be generalized to be true for all altitude conditions. By applying the standard corrections to the speed, fuel-flow, and torque terms in equation (3), this equation can be rewritten in terms of corrected quantities:

$$\begin{aligned} \frac{Q}{\delta_2} = & \left[\frac{\partial \left(\frac{Q}{\delta_2} \right)}{\partial \left(\frac{W_f \eta_b}{\delta_2 \sqrt{\theta_2}} \right)} \right]_o \left[\frac{W_f \eta_b}{\delta_2 \sqrt{\theta_2}} - \left(\frac{W_f \eta_b}{\delta_2 \sqrt{\theta_2}} \right)_o \right] \frac{1}{\delta_2 \sqrt{\theta_2}} + \\ & \left[\frac{\partial \left(\frac{Q}{\delta_2} \right)}{\partial \left(\frac{N}{\sqrt{\theta_2}} \right)} \right]_o (N - N_o) \frac{1}{\sqrt{\theta_2}} \end{aligned} \quad (7)$$

Equation (4) may be written as follows after both sides of the equation are divided by δ_2 and $\sqrt{\theta_2}$ and terms are collected:

$$\frac{Q}{\delta_2} = \frac{I \sqrt{\theta_2}}{\delta_2} \frac{d(\Delta N)}{dt \left(\frac{\sqrt{\theta_2}}{\delta_2} \right)} \quad (8)$$

When equation (8) is substituted in equation (7) the following equation results:

$$\frac{I \sqrt{\theta_2}}{\delta_2} \frac{d(\Delta N)}{dt \left(\frac{\sqrt{\theta_2}}{\delta_2} \right)} = \left[\frac{\partial \left(\frac{Q}{\delta_2} \right)}{\partial \left(\frac{W_f \eta_b}{\delta_2 \sqrt{\theta_2}} \right)} \right]_o \frac{\Delta(W_f \eta_b)}{\delta_2 \sqrt{\theta_2}} + \left[\frac{\partial \left(\frac{Q}{\delta_2} \right)}{\partial \left(\frac{N}{\sqrt{\theta_2}} \right)} \right]_o \frac{\Delta N}{\sqrt{\theta_2}} \quad (9)$$

FIGURE 2.—Graphical representation of engine differential equation for condition of constant partials.

(b) Engine variables corrected to compressor-inlet conditions relative to NACA standard atmospheric conditions at sea level.
 FIGURE 2.—Concluded. Graphical representation of engine differential equation for condition of constant partials.

By designating all the corrected quantities with a subscript c and by substituting the corrected curve slopes (fig. 2 (b)) for the partials, equation (9) may be written as

$$\frac{I\sqrt{\theta_2}}{\delta_2} \frac{d(\Delta N_c)}{dt} = a_{o,c} \Delta(W_f \eta_b)_c - b_{o,c} \Delta N_c \quad (10)$$

Equation (10) represents the dynamic behavior of the engine in terms of corrected engine variables at constant ram.

An examination of equation (10) reveals several pertinent facts concerning the behavior of engine acceleration under altitude conditions. First, the coefficients $a_{o,c}$ and $b_{o,c}$ are corrected quantities, which are nearly independent of altitude although they do depend on ram. Second, the burner efficiency affects the dynamic behavior of the engine. Burner efficiency may have a considerable effect on engine acceleration because the efficiency may change substantially under transients in fuel flow. Last, equation (10) indicates that the effective moment of inertia $I\sqrt{\theta_2}/\delta_2$ increases with increasing altitude. Thus the permissible temperature-limited acceleration is reduced with increasing altitude.

Equation (10) may be rearranged into the usual form for a differential equation describing a simple first-order lag system:

$$\frac{I\sqrt{\theta_2}}{\delta_2 b_{o,c}} \frac{d(\Delta N_c)}{dt} + \Delta N_c = \frac{a_{o,c}}{b_{o,c}} \Delta(W_f \eta_b)_c \quad (11)$$

With the equation written in this form, the coefficient of the derivative term is the time constant τ for the system. Equation (11) shows that the effect of increased altitude is to increase the engine time constant above its sea-level value by the factor $\sqrt{\theta_2}/\delta_2$.

EVALUATION OF ENGINE CONSTANTS FROM STEADY-STATE CHARACTERISTICS

In order to evaluate the slopes a_o and b_o , calculations were made for a typical turbojet engine with a centrifugal compressor, a sonic-flow turbine-nozzle diaphragm, and a fixed-

area exhaust nozzle by use of the compressor-performance charts and the thermodynamic relations in the engine. The method of making these calculations is presented in appendix B and is briefly outlined as follows: At constant ambient conditions, the compressor torque and the turbine torque were determined for a number of combinations of the parameters, turbine-inlet temperature and engine speed—parameters that are common to both the compressor and the turbine in a direct-coupled engine. The calculations were made by assuming constant compressor slip factor, burner efficiency, fuel-air ratio, burner pressure ratio, turbine efficiency, nozzle efficiency, and percentage accessory and gear loss. The difference in torque between the compressor and the turbine at any speed was considered an accelerating torque, and the parameter turbine-inlet temperature was expressed in terms of fuel flow. From these data, acceleration could be plotted in terms of engine speed and fuel flow for a set of constant ambient conditions. Because all the engine parameters may be corrected for altitude, the calculations were carried through in terms of corrected quantities.

The results of these calculations for two ram conditions corresponding to 0 and 340 miles per hour at sea level are shown in figure 3. The curves of the left-hand plot are essentially straight lines with variable spacing that cross-plot to the curved lines shown on the right-hand side. The curves of the left-hand side are nearly straight lines because of the constant efficiencies assumed in the calculations. If variable efficiencies are assumed, the shape of the curves will be changed depending on the variation of efficiencies assumed.

For the constant efficiencies assumed, the slope a_o is nearly constant over the power range and for large deviations from the steady-state region. The slope b_o , however, changes substantially over the power range and for large deviations from the steady-state region. This change in b_o indicates that some of the terms dropped from the expansion (equation (1)) may have significant value, especially for large deviations from the steady-state line.

Because the product of the moment of inertia and the reciprocal of b_o is the engine time constant, figure 3 indicates that the engine time constant depends to a considerable

extent on the operating point of the engine, which is roughly defined by the engine speed and altitude. The effect of ram on both a_o and b_o is rather small.

(b) Ram pressure ratio, 1.2.

FIGURE 3.—Relation among acceleration or accelerating torque, effective fuel flow, and engine speed corrected to compressor-inlet conditions relative to NACA standard atmospheric conditions at sea level as calculated from steady-state component data.

EVALUATION OF ENGINE CONSTANTS FROM TRANSIENT DATA

In order to determine the validity of the preceding analysis, an engine of the type for which the calculations were made was operated under conditions in which the fuel flow was rapidly changed through a series of magnitudes in order to obtain as large a region as possible of nonequilibrium operation. In attempting to impose operation of this nature on the engine, it was necessary to include components in the fuel system by means of which the fuel flow could be rapidly changed from one value to another. The system used consisted of two fuel lines from the pump to the fuel manifold arranged in parallel. The regular engine throttle was installed in one line and another engine throttle in series with a solenoid valve was installed in the other line. With the solenoid valve closed, the regular engine throttle was adjusted to give a selected lower engine speed. With the solenoid valve open, the auxiliary throttle was adjusted to give a selected higher engine speed. The fuel flows for any two steady-state engine speeds could thus be established and nonequilibrium conditions were obtained by opening or closing the solenoid valve.

Fuel flow was measured by means of a thin-plate orifice in the main fuel line with a differential-pressure gage to measure the pressure drop across the orifice. Engine speed was

FIGURE 4.—Typical time-domain curves of fuel flow and engine speed for engine transient experiments.

measured by a standard electric tachometer indicating revolutions per minute and time was measured by a clock reading in thousandths of a minute. The data were recorded simultaneously by a motion-picture camera at the rate of 12 frames per second. A preliminary investigation of the response rate of the fuel-flow and speed-measuring instrumentation showed that it was capable of following much more rapid rates of change than those encountered during the engine runs.

Typical examples of the imposed transients of fuel flow for accelerations and decelerations together with the resulting speed-time curves are shown in figure 4. The experimental data are shown in figure 5 in the same form as the calculated data in figure 3 except that, for the experimental data, the actual fuel flow is used instead of the effective fuel flow. The left-hand side of figure 5 was obtained from the data as follows: At a given speed, the acceleration and the fuel flow corresponding to the same instant in time were measured. This procedure was repeated for a number of transient runs resulting from various magnitudes of fuel-flow change. The right half of figure 5 was obtained by cross-plotting the faired curves of the left-hand side. The grouping of the data points from several runs indicates that a unique relation exists among torque, fuel flow, and speed, regardless of the manner in which the point is reached.

Near the steady-state region, the experimental data follow the results of the analysis and the calculations in that the slope $a_{o,c}$ is virtually constant over the power range and the slope $b_{o,c}$ varies substantially over the power range as indicated in figure 5. For accelerations in excess of about ± 5 percent of rated speed per second, the engine begins to exhibit large deviations from the calculated curves.

EFFECT OF ENGINE CONSTANTS ON CONTROLLED ENGINE

In matching controls to engines, the damping ratio is one of the criteria used to evaluate the degree of matching. Both engine coefficients and control coefficients appear in this damping term. For example, if it is assumed that a control operating on speed error to vary fuel flow according to the following equation

$$W_f = \int \beta(N_s - N) dt + \epsilon(N_s - N) + \sigma \frac{d(N_s - N)}{dt}$$

is applied to the engine described by equation (11), the combined equation for the system becomes

$$\left(\frac{I\theta_2}{a_{o,c}\eta_b} + \sigma\sqrt{\theta_2} \right) N_c'' + \left(\frac{b_{o,c}\delta_2\sqrt{\theta_2}}{a_{o,c}\eta_b} + \epsilon\sqrt{\theta_2} \right) N_c' + \beta\sqrt{\theta_2}N_c = \beta N_s + \epsilon N_s' + \sigma N_s''$$

where the primes signify derivatives with respect to time. The damping ratio for this expression is

$$\frac{\frac{b_{o,c}\delta_2}{a_{o,c}\eta_b} + \epsilon}{2\sqrt{\beta \left(\frac{I\sqrt{\theta_2}}{a_{o,c}\eta_b} + \sigma \right)}} \quad (12)$$

Thus if it is desired to maintain a constant value of the damping term, such as critical damping, it is evident from an examination of equation (12) that if an engine coefficient varies, some control coefficient must be varied in such a

FIGURE 5.—Relation among acceleration or accelerating torque, fuel flow, and engine speed corrected to compressor-inlet conditions relative to NACA standard atmospheric conditions at sea level as obtained from experimental data for a ram pressure ratio of 1.0

manner that the damping ratio remains substantially constant. Figures 6 and 7 are plots of $a_{o,c}$ and $b_{o,c}$, respectively, as functions of engine speed for the calculated data and the experimental data. The slope $a_{o,c}$ is virtually constant and will have little effect on the damping ratio but $b_{o,c}$ may change the damping ratio considerably for various operating points. If the variation is considered too great, it will be necessary to vary a control coefficient to compensate for the variation in $b_{o,c}$. Figure 7 indicates that $b_{o,c}$ varies almost directly with engine speed, which would

FIGURE 6.—Values of partial of torque with respect to fuel flow or effective fuel flow at steady-state point plotted against engine speed corrected to compressor-inlet conditions relative to NACA standard atmospheric conditions at sea level for calculated and experimental data.

indicate that one method of compensating for the variation of $b_{o,c}$ is to vary a control coefficient as a function of engine speed.

FIGURE 7.—Values of partial of torque with respect to engine speed at steady-state point plotted against engine speed corrected to compressor-inlet conditions relative to NACA standard atmospheric conditions at sea level for calculated and experimental data.

A plot of the corrected engine time constant as a function of engine speed is shown in figure 8. The time constant for this engine varies through a 4 to 1 range over the power range of the engine.

DISCUSSION

In general, the correlation between the calculated results and the experimental results is considered good and would be better if an approximation of burner efficiency were included in the calculations. This correlation indicates that for an engine of the type investigated, operating near the steady-state region, a good approximation of the dynamic characteristics can be made as soon as the component characteristics are available. Thus an engine may be

FIGURE 8.—Values of corrected engine time constant at steady-state point plotted against engine speed corrected to compressor-inlet conditions relative to NACA standard atmospheric conditions at sea level for calculated and experimental data.

designed, at least to a certain extent, to have good transient characteristics as well as good steady-state performance characteristics or at least a compromise may be reached between transient and steady-state performance if the two conflict in certain configurations.

Although the correlation in the steady-state regions is good, the correlation in the region of large accelerations can be regarded as only fair and in the region of large decelerations as poor. A possible explanation for the poorer correlation in the accelerating region is that the engine is approaching the acceleration blow-out region in the burners, which is a region of apparently low burner efficiencies. Temperature data taken during the experiments indicated that when excessive amounts of fuel were suddenly added combustion occurred through the turbine and the tail cone, which would result in low burner efficiencies during these periods.

The large deviations between calculated and observed values of deceleration seem to have no obvious explanation. The very large decelerations observed would indicate that very large reductions in torque output of the turbine occurred. These reductions can be only partly accounted for by the normal steady-state effect of a reduction in temperature on turbine torque. The reduction in temperature that did occur may possibly have caused a rotation of the

turbine-entrance-velocity vector relative to the blade to a condition of negative angle of attack. Such a condition corresponds to a high value of turbine-velocity ratio for which the turbine efficiency is rapidly falling. The existence of a negative angle of attack together with the increased air flow and consequently increased compressor torque that results from a reduction in temperature at constant speed could conceivably cause large decelerating torques. The existence of a negative angle of attack would also explain the position of the sharp breaks in the curves of figure 5, because at low speeds the steady-state angle of attack is greater than at high speeds, which are near the design condition; therefore a greater reduction in temperature at constant speed is necessary to cause negative angles of attack and a consequent sharp change in curve slope. The preceding discussion would seem to indicate a possible explanation for the sharp change of slope for deceleration points but does not explain the vertical parts of the curves, which indicate that various decelerations occur with the same turbine-inlet temperature. A check of the data, however, indicated that along the vertical part of a constant-speed line of figure 5 the deceleration value was consistent with the rate of change of fuel flow; that is, the deceleration value increased with increasing rates of change of fuel flow. Thus, if the burner efficiency reduced as a function of the rate of change of fuel flow so that the temperature was reduced, the vertical lines of figure 5 seem logical.

CONCLUSIONS

The following conclusions are drawn from an analysis of the dynamic behavior of, and from transient data obtained from, a typical turbojet engine with a centrifugal compressor, a sonic-flow turbine-nozzle diaphragm, and a fixed-area exhaust nozzle:

1. Accelerating torque is a function of fuel flow and engine speed. A linear differential equation approximately represents the transient behavior of the engine speed for accelerations less than approximately 5 percent of rated speed per second.

2. The transient equation of the engine may be obtained from the steady-state performance of the engine components to a degree of accuracy that will permit the prediction of the engine transient characteristics as soon as the component characteristics are available.

3. A transient equation for engine speed may be derived including the effects of altitude by the use of corrected engine variables in the derivation.

4. The manner in which the control constants should be varied to compensate for the changes in engine characteristics with altitude and with engine speed may be predicted from an analysis of the combined engine and control equation.

APPENDIX B

ENGINE-TRANSIENT-CHARACTERISTIC CALCULATIONS

In general, the method used to calculate the characteristics of an engine operating under transient conditions involves determining the difference between compressor torque and turbine torque for assumed values of engine speed, turbine-inlet temperature, ambient conditions, and ram pressure ratio. Figure 9 is a chart of typical compressor characteristics obtained from unpublished data. For assumed values of ram pressure ratio, ambient conditions, engine speed, and turbine-inlet temperature, corresponding values of compressor pressure ratio and corrected air flow may be determined. The torque required by the compressor for the assumed conditions may then be calculated from the following equations:

$$\frac{T_3}{T_2} = 1 + 0.5079 \times 10^{-8} \left(\frac{N}{\sqrt{\theta_2}} \right)^2 \quad (\text{B1})$$

$$Q_c = c_{p,c} (T_3 - T_2) \frac{W_a (778) (60)}{2\pi N} \quad (\text{B2})$$

Equation (B1) is developed for an assumed slip factor of

0.925 and a compressor rotor diameter of 2.5 feet. The definitions of the symbols used are given in appendix A.

The equation for the torque output of the turbine is similar to equation (B2) in that it involves the temperature drop through the turbine, the gas flow, and the speed. The speed and the gas flow are known from the assumed conditions and the resulting compressor point. The temperature drop through the turbine, however, must be determined for the operating point. In the absence of a complete turbine-performance map, general thermodynamic relations defining typical turbine operation must be utilized. A relation between turbine pressure ratio P_4/P_5 and turbine temperature ratio $\sqrt{T_4/T_5}$ is determined by assuming a constant turbine efficiency as expressed by the following equation:

$$\eta_T = \frac{1 - \frac{T_5}{T_4}}{1 - \left(\frac{P_5}{P_4} \right)^{\frac{\gamma-1}{\gamma}}} \quad (\text{B3})$$

FIGURE 9.—Compressor characteristics corrected to compressor-inlet temperature and pressure relative to NACA standard atmospheric conditions at sea level. Curves of constant ratio of turbine-inlet temperature to compressor-inlet temperature for engine are superimposed on compressor-characteristic curves. (Obtained from unpublished data.)

FIGURE 10.—Relation between turbine total-pressure ratio and total-temperature ratio at constant turbine efficiency of 0.83.

For this analysis η_T was assumed at 83 percent, and γ_4 was assumed at 1.33. The resulting relation between $\sqrt{T_4/T_5}$ and P_4/P_5 is plotted in figure 10.

Because critical flow exists in the turbine nozzles over the

power range, the corrected gas flow through the turbine nozzles will have a constant value. For this engine, unpublished data have indicated that the corrected gas flow will have a value expressed by the following equation:

$$\frac{W_g \sqrt{\left(\frac{T_4}{519}\right) \left(\frac{\gamma_4}{1.4}\right)}}{\left(\frac{P_4}{14.7}\right) \left(\frac{\gamma_4}{1.4}\right)} = 41.6 \text{ lb/sec} \quad (\text{B4})$$

This equation may be expanded as follows:

$$\frac{W_g \sqrt{\frac{T_5}{519}}}{A \frac{P_5}{14.7}} = \frac{41.6 \sqrt{\frac{\gamma_4}{1.4}} \left(\frac{P_4}{P_5}\right)}{A \sqrt{\frac{T_4}{T_5}}}$$

For an effective exhaust-nozzle area of 1.87 square feet and with γ_4 assumed constant at 1.33, the preceding equation becomes

$$\frac{W_g \sqrt{\theta_5}}{A \delta_5} = \frac{21.75 \frac{P_4}{P_5}}{\sqrt{\frac{T_4}{T_5}}} \quad (\text{B5})$$

FIGURE 11.—Variation of exhaust-nozzle pressure ratio with gas flow per unit exhaust-nozzle area corrected to total pressure and temperature in the exhaust nozzle relative to NACA standard atmospheric conditions at sea level. (Obtained from unpublished data.)

FIGURE 12.—Relation of exhaust-nozzle pressure ratio and turbine total-pressure- and temperature-ratio parameters for exhaust-nozzle area of 1.87 square feet.

From equation (B5) and figure 11, which is plotted from unpublished data, values can be obtained for a plot of P_5/p_0 as a function of $(P_4/P_5)/\sqrt{T_4/T_5}$ for an exhaust-nozzle area of 1.87 square feet. This relation is shown in figure 12.

FIGURE 13.—Relation between engine-pressure ratio and turbine-pressure ratio for exhaust-nozzle area of 1.87 square feet.

Figures 10 and 12 can then be used to obtain P_4/p_0 as a function of P_4/P_5 . This relation is shown in figure 13.

The turbine torque for each condition for which compressor torque was computed can now be found. In this analysis, it was assumed that P_4/P_5 was constant at 0.95, which determines P_4 for each compressor point, and that W_g/W_a was constant at 1.015, which determines W_g for each compressor point. With the use of the value of P_4 obtained by applying one of these assumed relations to the value of P_3 obtained from the compressor-torque calculations, $\sqrt{T_4/T_5}$ can now be obtained through the use of figures 13 and 10, successively. The turbine torque corresponding to the assumed conditions of ram pressure ratio, ambient conditions, engine speed, and turbine-inlet temperature can then be computed from the following equation:

$$Q_T = c_{p,T}(T_4 - T_5) \frac{W_o(778)(60)}{2\pi N} \quad (B6)$$

The accelerating torque can then be calculated from the following equation in which 1 percent of the turbine torque or power was assumed lost to the accessories and to gear and bearing friction:

$$Q = 0.99 Q_T - Q_C = I\alpha \quad (B7)$$

A plot of angular acceleration as a function of engine speed, turbine-inlet temperature, and effective fuel flow $W_f\eta_b$ for ram conditions corresponding to an airplane velocity of 0 and 340 miles per hour at sea level, corrected to NACA standard sea-level conditions is shown in figure 14. The effective fuel flows were obtained by use of the following equation, which assumes no time lag between temperature and fuel flow:

$$W_f\eta_b = \frac{W_a(h_4 - h_3)3600}{H_f} \quad (B8)$$

The values of h_4 and h_3 corresponding to the assumed temperature T_4 and the temperature T_3 calculated from equation (B1) can be found from a table of enthalpies. Figure 3

was obtained by plotting the constant-speed lines of figure 14 and then cross-plotting to obtain the constant-fuel-flow curves.

REPORT 1012

INVESTIGATION OF THE NACA 4-(5)(08)-03 AND NACA 4-(10)(08)-03 TWO-BLADE PROPELLERS AT FORWARD MACH NUMBERS TO 0.725 TO DETERMINE THE EFFECTS OF CAMBER AND COMPRESSIBILITY ON PERFORMANCE¹

By JAMES B. DELANO

SUMMARY

As part of a general investigation of propellers at high forward speeds, tests of two-blade propellers having the NACA 4-(5)(08)-03 and NACA 4-(10)(08)-03 blade designs were made in the Langley 8-foot high-speed tunnel through a range of blade angle from 20° to 60° for forward Mach numbers from 0.165 to 0.70 to determine the effect of camber and compressibility on propeller characteristics. Results previously reported for similar tests of a two-blade propeller having the NACA 4-(3)(08)-03 blade design are included for comparison.

Blades of high design camber were more efficient than blades of low design camber for operation at high power loadings. The blade of highest camber gave efficiencies 15 to 25 percent higher than the efficiencies of the low-camber and medium-camber blades for high power loadings at advance ratios corresponding to take-off and climb at low Mach numbers. The NACA 4-(5)(08)-03 propeller generally gave peak efficiencies 2 to 5 percent higher than those for the NACA 4-(3)(08)-03 propeller and 3 to approximately 12 percent higher than those for the NACA 4-(10)(08)-03 propeller. These higher efficiencies were due mainly to reduced compressibility losses. At the design blade angle of 45°, the critical tip Mach number for maximum efficiency was 0.01 higher for the NACA 4-(5)(08)-03 propeller than for the NACA 4-(3)(08)-03 propeller, which began to show compressibility losses at a tip Mach number of approximately 0.90. The NACA 4-(10)(08)-03 propeller began to show compressibility losses at a tip Mach number as low as 0.70 but, because of the large power-absorbing capacity of this propeller, produced about 46 percent more thrust than the NACA 4-(5)(08)-03 propeller for a high-speed operating condition corresponding to a tip Mach number of 0.86, a forward Mach number of 0.53, and an advance ratio of 2.48.

INTRODUCTION

Many airplanes now take off and climb with propellers at least partly stalled, and the tendency to use increasing powers may aggravate a condition that is already serious. Flight at high altitudes also may necessitate propeller operation at high lift coefficients, which would increase possible stall and compressibility effects and result in a reduction of propeller efficiency.

The National Advisory Committee for Aeronautics has attempted to improve propeller performance by conducting a general investigation of propellers at high forward speeds.

This investigation included the effects on propeller characteristics of compressibility, blade solidity, and blade-section camber. The research program included tests of propellers of a sufficient range of blade forms to make possible the study of changes in blade shapes that might be required as a consequence of compressibility effects.

The effects of compressibility and solidity on performance as determined from tests of the NACA 4-(3)(08)-03 and NACA 4-(3)(08)-045 two-blade propellers (reference 1) constituted the initial phase of a general investigation of propellers at high forward speeds. The effects of camber and compressibility on performance as determined from tests of the NACA 4-(5)(08)-03 and NACA 4-(10)(08)-03 two-blade propellers constituted the second phase of the investigation and are presented herein. These results are compared with results of reference 1 for the NACA 4-(3)(08)-03 propeller, in order to indicate the effects of section design camber for propellers operating over a wide range of forward Mach number. These three blade designs cover the practical range of blade section camber.

ϕ	aerodynamic helix angle, degrees $(\phi_0 + \alpha_i)$
ϕ_0	geometric helix angle, degrees $\left(\tan^{-1} \frac{JR}{\pi r}\right)$

APPARATUS, METHODS, AND TESTS

The apparatus and methods described in reference 1 were used in the present investigation. The investigation was conducted in the Langley 8-foot high-speed tunnel. A photograph showing the model setup is given as figure 1.

The blades of the propellers investigated were designed for three-blade propellers to produce minimum induced energy losses (profile drag assumed equal to zero) at a blade angle of approximately 45° at the 0.7-radius station. The blade sections are late-critical-speed sections of the NACA 16 series (reference 2); methods and principles employed in the design of the blades are discussed in reference 3. The blades differ only in design camber and are designated as NACA 4-(3)(08)-03 (low camber, reference 1), NACA 4-(5)(08)-03

(medium camber), and NACA 4-(10)(08)-03 (high camber).

The designation numbers describe the propellers. The number (or numbers) of the first group is the diameter in feet; the number (or numbers) of the second group (enclosed within the first set of parentheses) is the design lift coefficient (in tenths) of the blade section at the 0.7-radius station; the numbers of the third group (enclosed within the second set of parentheses) are the thickness ratio of the blade section at the 0.7-radius station; and the numbers of the fourth group are the blade solidity expressed as the ratio of the blade chord at the 0.7-radius station to the circumference of the circle having a radius 0.7 of the propeller tip radius. The NACA 4-(10)(08)-03 propeller thus has a diameter of 4 feet and the blade section at the 0.7-radius station has a design lift coefficient of 1.0, a thickness ratio of 0.08, and a blade solidity of 0.03.

Blade-form curves for the propellers are presented in figure 2. A photograph of one of these blades and a comparison of the sections at the 0.7-radius station are given as figure 3.

The range of this investigation was the same, within power limitations, as that of reference 1. The range of blade angle and tunnel-datum Mach number is given in table I.

REDUCTION OF DATA

The data have been reduced to the usual thrust and power coefficients and efficiency and have been corrected for the propulsive effects of the cowling and spinner and for tunnel-wall constraint. The tunnel-wall constraint necessitated a velocity correction to free-air conditions and a model-drag correction because of the buoyancy effect. The methods involved in making these corrections are discussed in reference 1.

FIGURE 2.—Blade-form curves.

FIGURE 1.—Setup for testing propellers in the Langley 8-foot high-speed tunnel.

FIGURE 3.—Typical test blade and comparison of sections at 0.7 radius.

Thrust.—The thrust coefficient was determined from the propulsive thrust, that is, the net measured force minus the drag of the model without the propeller and minus the thrust due to the buoyancy effect (see reference 1).

Velocity correction due to tunnel-wall constraint.—The equivalent free-stream velocity corresponding to the thrust and torque of the propeller measured at each rotational speed differs from the tunnel-datum velocity (tunnel empty) because of the flow constraint produced by the tunnel walls.

^a Except for NACA 4-(10)(08)-03 propeller.

^b Except for NACA 4-(3)(08)-03 and NACA 4-(5)(08)-03 propellers.

The velocity correction, which has been applied to the calculation of advance ratio, is presented in figure 4 as the ratio of free-air velocity to the tunnel-datum velocity (tunnel empty) as a function of the thrust disk-loading coefficient. The tunnel-wall correction was found to be dependent only on the thrust disk-loading coefficient for the range of tunnel speed and propeller operation used in this investigation.

The tunnel-datum Mach number has not been corrected for tunnel-wall constraint. For the range of velocity shown in figure 4, the factors required to correct the tunnel-datum velocity and tunnel-datum Mach numbers to the free-stream condition are essentially equal.

RESULTS AND DISCUSSION

The basic characteristics for the NACA 4-(5)(08)-03 and NACA 4-(10)(08)-03 two-blade propellers are presented in figures 5 and 6, respectively. For each value of the tunnel-datum Mach number the propeller thrust coefficient, power coefficient, and efficiency are plotted against advance ratio. The variation of tip Mach number with advance ratio is also included. As used in this report, the tunnel-datum Mach number M is not corrected for the effects of tunnel-wall constraint. The free-stream Mach number can be obtained by applying the tunnel-wall corrections presented in figure 4 to the tunnel-datum Mach number. Similarly, the corrected tip Mach number can also be obtained.

Effect of camber on thrust coefficient.—The primary effect of using propeller blades of increased design camber (increased design lift coefficient) is to increase the power absorbed by the blades and consequently to increase the thrust. A typical illustration of the increase in thrust produced by increasing the design camber is shown in figure 7 in which the thrust coefficients for the high-camber, medium-camber, and low-camber propellers for a blade angle of 45° and a forward Mach number of 0.23 are compared. The power-coefficient curves are similar and hence are not shown. For cases in which take-off and climb performances are of prime importance, the increased thrust produced by the blades of high design camber may determine the design; greater thrusts may be produced with no increase in propeller weight. The maximum thrust coefficient and the thrust coefficient for maximum efficiency also increase with an increase in design camber, as shown in figures 8 and 9 for Mach

FIGURE 7.—Effect of design camber on thrust coefficient. $M=0.23$; $\beta_{0.75R}=45^\circ$.

FIGURE 8.—Effect of design camber on maximum thrust coefficient. $M=0.165$.

FIGURE 9.—Effect of design camber on thrust coefficient for maximum efficiency. $M=0.35$.

numbers of 0.165 and 0.35, respectively. The percentage of increase in thrust is less than the percentage of increase in corresponding design camber. The maximum thrust coefficients for the medium-camber propeller are 7 to 11 percent greater than for the low-camber propeller. The maximum thrust coefficients for the high-camber propeller are 41 to 46 percent greater than for the low-camber propeller. The increases in thrust coefficient for maximum efficiency are

much greater than the increase in maximum thrust coefficient. The thrust coefficients at maximum efficiency are 30 to 79 percent greater for the medium-camber propeller and 105 to 165 percent greater for the high-camber propeller than for the low-camber propeller.

Operation at high angles of attack may cause the blade sections to become stalled or nearly stalled so that the propeller efficiency is decreased because of increased profile-drag losses. The pressure distribution over these blade sections is therefore far from optimum and has high peaks that have a tendency to cause flow separation or to initiate compressibility shock. The use of blades of high design camber, however, makes it possible for the blade sections to operate at high section lift coefficients, which are obtained at angles of attack much lower than for blades of low design camber; thus, the tendency of the flow to separate is reduced and stalled conditions are largely eliminated. Since the pressure distribution about the sections may closely approximate the design distribution, the profile drag and the tendency for shock to be initiated are reduced.

Effect of camber and power loading on efficiency.—The effect of blade power loading on propeller efficiency for the high-camber, medium-camber, and low-camber propellers is shown in figure 10 for a forward Mach number of 0.165. Values of the power coefficient of about 0.10 for these propellers represent operation at high lift coefficients for values of the advance ratio corresponding to take-off and climb. For this condition, the propeller efficiency decreases very rapidly as the power coefficient is increased because of the increased profile-drag losses and the failure of the lift to increase beyond the maximum section lift coefficient with further increase of angle of attack. The ideal efficiency computed from the momentum theory is also shown in figure 10 for comparison. The divergence of the measured efficiency from the ideal efficiency emphasizes the magnitude of the profile-drag and induced losses.

The effect of design camber for constant values of power coefficient is shown in figure 11 for a forward Mach number of 0.165. At low advance ratios corresponding to take-off and climb, increased camber gives increased efficiency at high power coefficients. At these high power coefficients, the high-camber blade is 15 to 25 percent more efficient than the low-camber and medium-camber blades. At low advance ratios and for low power coefficients, the high-camber blade is approximately 5 percent less efficient than the low-camber and medium-camber blades. These variations emphasize the necessity for choosing the correct blade camber to meet operational requirements. The high-camber blade is generally more efficient than the low-camber and medium-camber blades up to values of the advance ratio approximately 10 times the value of the power coefficient. The medium-camber blade is generally as much as 5 percent more efficient than the low-camber blade for the same operating

range. These results suggest that a satisfactory compromise propeller may be designed by proper selection of the design camber.

Single-station analysis of camber effects.—In order to show the effect of design camber and operating lift coefficients on propeller section efficiency, the results of tests of the NACA 16-series airfoil sections of 9-percent thickness (reference 2) were chosen as representative of the section at the 0.7-radius station. Since this analysis is not an attempt to explain or present compressibility effects, data at a Mach number of 0.45 are used. It can be shown that the section efficiency is given by

$$\eta = \frac{\tan \phi_0}{\tan (\phi + \gamma)} \quad (1)$$

Figure 12 shows the results obtained by use of equation (1). For a given operating lift coefficient, the induced angle of attack for all the sections is the same; hence, the efficiency shows the effect of lift-drag ratio. The most obvious result is that the sections with design lift coefficients between 0.3 and 0.5 are the most efficient, because these sections have the highest lift-drag ratios at maximum efficiency. For sections with design lift coefficients of 0.3 and lower, the maximum efficiency occurs at operating lift coefficients greater than the design lift coefficients. For sections with design lift coefficients higher than 0.3, the maximum efficiency occurs at operating lift coefficients lower than the design lift coefficient. The maximum attainable efficiency at any blade operating lift coefficient is represented by the envelope of the efficiencies in figure 12. The greatest efficiency attainable for operation at a given lift coefficient occurs when the section has a design lift coefficient equal to the operating lift coefficient.

Effect of compressibility on maximum efficiency.—The envelope efficiencies for the high-camber, medium-camber, and low-camber propellers are presented in figure 13 for forward Mach numbers from 0.23 to 0.70. The values of advance ratio at which propeller tip Mach numbers of 0.9, 1.0, and 1.1 are reached are indicated by vertical dash lines labeled with the value of M_t . The medium-camber propeller gave the highest efficiencies for all advance ratios and for forward Mach numbers up to 0.53. In most cases, the medium-camber propeller was 2 to 5 percent more efficient than the low-camber propeller. The high-camber propeller gave peak efficiencies 3 to approximately 12 percent lower than those for the medium-camber propeller; the higher efficiency losses were due mainly to compressibility effects. At tip Mach numbers greater than approximately 0.90, the low-camber and medium-camber propellers showed compressibility losses. The high-camber propeller, however, showed an appreciable compressibility loss at a tip Mach number considerably below 0.90, but the efficiencies were still above 82 percent.

 FIGURE 11.—Effect of design camber and power loading on efficiency. $M=0.165$.

FIGURE 12.—Effect of design camber on blade-section efficiency, from single-station analysis using NACA 16-series sections. $\frac{r}{R}=0.7$; $\frac{h}{b}=0.09$; $\phi=44^\circ$; $M=0.45$.

The effect of compressibility on maximum efficiency is shown in figure 14 for a blade angle of 45° . Maximum efficiency differed very little for the low-camber and medium-camber propellers with critical tip Mach numbers of approximately 0.90 and 0.91, respectively. The high-camber propeller begins to show compressibility losses at a tip Mach number of 0.70, but the rate of loss is less than that for the low-camber and medium-camber propellers. The low critical speed of the propeller with the highest camber obviously excludes the use of this propeller for very efficient high-speed operation. The early compressibility losses for the high-camber propeller are due, in part at least, to the high power absorbed. If the low-camber and medium-camber propellers absorbed the same power as the high-camber propeller, these propellers would have to operate at high angles of attack; this operation would produce high pressure peaks and perhaps earlier and more extensive compressibility losses.

In order for the low-camber and medium-camber propellers to absorb the same power as the high-camber propeller and still operate at high efficiencies, a considerable increase in solidity would be necessary. The large power-absorbing capacity of the high-camber propeller, however, makes it useful for conditions of operation at which large values of thrust are required, even at high speeds. For example, the influence of design camber on maximum efficiency and on the power absorbed at maximum efficiency is presented in

figure 15 for an advance ratio of 2.48 at forward Mach numbers of 0.23 and 0.53 (tip Mach numbers of 0.37 and 0.86, respectively). For these conditions, the high-camber propeller shows a compressibility loss of 8 percent. The high-camber propeller absorbs 55 percent more power than the medium-camber propeller and 75 percent more power than the low-camber propeller at a forward Mach number of 0.53. The corresponding differences in efficiency are reductions of 9 and 10 percent, which result in net thrust increases of 46 and 65 percent, respectively, for the high-camber propeller; in addition, these increases in thrust are obtained with no increase in propeller weight.

Effect of compressibility and power disk loading on maximum efficiency.—The effects of power disk-loading coefficient P_c and compressibility on maximum efficiency are shown in figure 16. The curve for the ideal efficiency obtained from axial-momentum considerations is also shown. The ideal efficiency deviates from 100 percent solely because of the induced loss due to increasing the axial velocity of the air in the slipstream. The additional losses for an actual propeller, however, are due to profile-drag and rotational induced losses. The induced losses for these propellers are small, and the differences shown between the ideal and the measured efficiencies are principally due to blade drag loss. At a given value of the forward Mach number, increased values of P_c correspond to loadings at low values of the advance ratio.

FIGURE 13.—Effect of design camber and compressibility on envelope efficiency.

 FIGURE 14.—Effect of compressibility on maximum efficiency. $\beta_{0.75R} = 45^\circ$.

 FIGURE 15.—Effect of blade-section design lift coefficient on maximum efficiency and power absorbed at maximum efficiency. $J = 2.45$.

FIGURE 16.—Effect of power disk loading and compressibility on maximum efficiency.

At low values of the forward Mach number (fig. 16 (a)), for example, the maximum-efficiency curves for the three propellers are parallel for high values of P_c and are relatively close to the ideal-efficiency curve. This agreement is expected, because these propellers have approximately the optimum pitch distributions for these values of P_c and because the profile-drag and induced losses are not expected to change very much. Since at a constant forward Mach number the high values of P_c for each curve correspond to operation at the highest tip speeds for that condition, compressibility losses would appear at the high values of the power disk-loading coefficient. No compressibility losses appear for the low forward Mach numbers. For all propellers, large losses begin to appear at a forward Mach number of 0.53 and are most severe for the low-camber propeller and

least severe for the medium-camber propeller. At a Mach number of 0.65, the high-camber propeller appears to be more efficient than the other propellers for operation at the high power disk-loading coefficients. Of particular interest is the greatly reduced range of power disk-loading coefficient for which the maximum efficiencies obtained at low Mach numbers can be maintained at high forward Mach numbers. Similar results are shown in reference 1. At forward Mach numbers of 0.53 or greater, the range of power disk-loading coefficient that gives high efficiencies for the low-camber propeller is greatly reduced because of compressibility losses. Previous results (reference 1) have indicated that the range of power disk-loading coefficient for high efficiency may be selected by change of blade solidity. The results reported herein also indicate that the same effect can be produced by

change of camber. This effect is particularly pronounced for forward Mach numbers of 0.53 and 0.65 (figs. 16 (d) and 16 (e)). The medium-camber and high-camber propellers can operate more efficiently at high values of the power disk-loading coefficient, but compressibility effects have considerably lowered the efficiencies. Changing the design camber thus offers another possibility of operating at high power disk loadings without too much loss in maximum efficiency.

The power disk-loading coefficient for which low-speed efficiencies may be maintained at high speeds can also be increased by using a greater number of similar blades, as was pointed out in reference 1. For operation at very high speeds, particular consideration must therefore be given to the aerodynamic design. The design of a propeller then approaches the design for a specific condition of operation to obtain high efficiencies because of the reduced range of available power disk loading.

CONCLUSIONS

Two-blade propellers designated the NACA 4-(5)(08)-03 (medium camber) and the NACA 4-(10)(08)-03 (high camber) propellers have been investigated in the Langley 8-foot high-speed tunnel through a range of blade angles from 20° to 60° for forward Mach numbers from 0.165 to 0.70 to determine the effect of camber and compressibility on propeller characteristics. The results of these tests and comparisons with results obtained from previous tests of the NACA 4-(3)(08)-03 (low camber) propeller indicated the following conclusions:

1. Propellers of high design camber were more efficient than propellers of low design camber for operation at high power coefficients. The propeller of highest camber gave efficiencies 15 to 25 percent greater than the efficiencies of the low-camber and medium-camber propellers for high power coefficients at advance ratios corresponding to take-off and climb at low Mach numbers.

2. The medium-camber propeller generally gave peak efficiencies 2 to 5 percent higher than the low-camber

propeller and 3 to approximately 12 percent higher than the high-camber propeller. The high-camber propeller was operating at much higher power coefficients, which led to early compressibility effects.

3. The critical tip Mach number for maximum efficiency at the design blade angle of 45° was 0.01 higher for the medium-camber propeller than that for the low-camber propeller, which began to show compressibility losses at a tip Mach number of approximately 0.90. The high-camber propeller, which was operating at higher power coefficients than the other propellers, showed the largest compressibility losses. The compressibility losses for the high-camber propeller began at a tip Mach number as low as 0.70 but efficiencies of more than 82 percent were still maintained.

4. For a forward Mach number of 0.53 and an advance ratio of 2.48 (tip Mach number of 0.86), the high-camber propeller showed a compressibility loss of 8 percent in maximum efficiency but, because of the large power-absorbing capacity of this propeller, produced about 65 percent more thrust than the low-camber propeller and 46 percent more thrust than the medium-camber propeller.

5. The range of power disk-loading coefficient over which high efficiencies could be obtained was greatly reduced at high speeds.

REPORT 1013

EFFECTS OF WING FLEXIBILITY AND VARIABLE AIR LIFT UPON WING BENDING MOMENTS DURING LANDING IMPACTS OF A SMALL SEAPLANE ¹

By KENNETH F. MERTEN and EDGAR B. BECK

SUMMARY

A smooth-water-landing investigation was conducted with a small seaplane to obtain experimental wing-bending-moment time histories together with time histories of the various parameters necessary for the prediction of wing bending moments during hydrodynamic impact. The experimental results were compared with calculated results which include inertia-load effects and the effects of air-load variation during impact. The responses of the fundamental mode were calculated with the use of the measured hydrodynamic forcing functions. From these responses, the wing bending moments due to the hydrodynamic load were calculated according to the procedure given in R. & M. No. 2221. This comparison of the time histories of the experimental and calculated wing bending moments showed good agreement both in phase relationship of the oscillations and in numerical values.

The effects of structural flexibility on the wing bending moment were large, the dynamic component of the total moment being as much as 97 percent of the static component. Changes in the wing bending moment due to the variation in air load during impact were of about the same magnitude as the static water-load component.

INTRODUCTION

Recent trends in the design of aircraft have led to an important increase of the stresses produced in wings by landing impacts. Two significant factors contributing to these increased stresses during landing are an increased proportion of the airplane weight in the wings and an increased structural flexibility, since, in most cases, these factors have caused the ratios of the times to peak of the applied landing loads to the period of the fundamental mode to approach a critical value.

Several simplified methods have been developed for determining the inertia loads in wing structures during landing impacts, and studies have been made of the landing-impact inertia loads in simplified structures with the use of the principles of these methods. Although experimental investigations have been made to determine the magnitudes of inertia loads in actual airplane structures, little correlation of theory and experiment has been made concerning the nature and magnitude of inertia loads in airplane wings during actual landing impacts.

Another aspect of the problem of wing loads during landing is the variation of air load due to changes of attitude and flight path during impact. The importance of this change in air load has been the subject of some speculation but little investigation.

In order to evaluate the importance of the various components of the load, including dynamic effects and variation in air load, data were obtained during full-scale landing tests of a small seaplane to provide a comparison of actual wing loads with those predicted by a simplified method (reference 1).

The present report gives a comparison of the theoretical and experimental wing loads, in the form of time histories of the wing bending moments, and discusses the contributions of each of the components of the moment (static water-load moment, dynamic water-load moment, and air-load moment) to the total. The static and dynamic components of the total moment were calculated and combined according to the procedure of reference 1, with the responses of the fundamental mode being calculated from the recorded time histories of the applied forces. The air-load component was calculated by a simplified method which is described in this report.

APPARATUS AND INSTRUMENTATION

The airplane used in the present investigation was a small two-engine seaplane (fig. 1). Pertinent information about the seaplane is given in table I, and additional information may be obtained from reference 2. The frequency and shape of the fundamental wing bending mode were found from ground vibration tests and are given in table II and figure 2. The spanwise weight distribution is also given in table II.

The trim variation was measured with a gyroscopic trim recorder mounted in the cabin floor. The airspeed was measured with an NACA airspeed recorder, pitot-static-tube type, mounted above the cabin. Accelerations of the center of gravity were obtained from an NACA optical-recording three-component accelerometer mounted securely in the fuselage near the center of gravity. The time of contact was determined from a water-contact indicator located on the keel at the main step. The hull immersions were determined from pressure gages installed along the bottom of the hull. The wing bending moments were measured by means of a strain gage mounted on the wing main spar 9 inches from the center line of the seaplane (hereinafter referred to as station 9).

The estimated accuracies of the experimental data based on calibration, instrument, and reading error are as follows:

Horizontal velocity, V_h , feet per second	± 4
Trim angle, τ , degrees	± 0.25
Load factor, n , multiples of g	± 0.2
Initial wing lift, L_0 , multiples of g	± 0.05
Total wing bending moment, M_T , pound-inches	$\pm 0.05 \times 10^6$

TEST PROCEDURE

The landing-impact tests were made in smooth water. During these landing tests, airspeed, trim variation, center-of-gravity accelerations, and wing-spar bending moments were recorded. The landings were made at horizontal velocities ranging from 95.4 to 112.0 feet per second, trim angles ranging from 3.00° to 7.83° , and initial flight-path angles ranging from 2.0° to 4.4° . The resulting maximum center-of-gravity accelerations normal to the keel line ranged from $1.10g$ to $1.96g$ and the duration of the impacts varied from 0.63 to 0.87 second. The times to peak of these normal accelerations ranged from 0.10 to 0.36 second. Values of these parameters and other pertinent information for all the tests are presented in table III.

THEORY

WILLIAMS' METHOD

In reference 1 a method was proposed for calculating the dynamic effect of an impulsive load applied to an elastic structure. Basically, the method follows classical normal-mode vibration theory by considering the total response of the elastic structure to a forcing function at any instant to be the summation of the responses of all of its normal modes at that instant. However, a unique feature of the method is that the total response of each mode is separated into a static and a dynamic component, and the stress due to the sum of the static components of the responses of all the modes is found in one calculation by rigid-body analysis. This stress is referred to as the static-load stress. The stress of each mode due to its dynamic component of response is found separately. The total stress is the sum of the static-load stress and the dynamic components of stress for the significant modes. Time histories of stress are found in these calculations and thus phase relationships of the modes are considered when the stresses for each mode are added.

AIR-LOAD VARIATION

In determining the effect of air-load variations on the wing bending moment during impact, the air load was assumed to change instantaneously with change in angle of attack and the rate of change in air load was assumed to be slow enough to neglect excitation of structural dynamic response. Also, the ratio of air-load bending moment to lift was assumed to be constant for all impacts. On the basis of these assumptions, the air-load moment at any time during the impact M was related to the lift L and the ratio of bending moment to lift at time of contact M_0/L_0 by the following equation:

$$M = \left(\frac{M_0}{L_0} \right) L$$

An average value of M_0/L_0 , obtained from the measured values of lift and moment at time of contact, was used in this equation. The variation of lift L was determined from time histories of the angle of attack and velocity in conjunction with a lift curve (C_L plotted against α) determined for the wing with flaps deflected. This lift curve was determined by fairing a line with the slope of the available lift curve without flaps deflected through the values of C_L computed for all the impacts from the measured velocity,

angle of attack, and center-of-gravity acceleration at time of contact. With the variation in total air-load moment thus determined, the change in air-load wing bending moment during impact ΔM was found from the following equation:

$$\Delta M = M_0 - M$$

CALCULATIONS AND RESULTS

The variations of the wing angle of attack and velocity during impact necessary for computing the changes in air-load bending moment were determined for each impact from the recorded data in the following manner. The accelerations normal and parallel to the keel line, obtained from the three-component center-of-gravity accelerometer, were plotted (fig. 3). After the trim-angle variation (fig. 4 (a)) was taken into account, these accelerations were resolved into vertical and horizontal components. Integration of the time histories of these accelerations over the duration of the impact produced time histories of the changes in vertical and horizontal velocities. Since the vertical velocity at the time of contact was not accurately known, the initial

(a) Acceleration parallel to seaplane keel line during impact.
(b) Acceleration normal to seaplane keel line during impact.
FIGURE 3.—Typical accelerometer records and fairings.

velocity was determined so that integration of the time-history curve over the duration of the impact resulted in a final vertical displacement of zero. (The duration of the impact is defined as the interval between the time of contact and the time when the center of gravity again reached its initial height above the mean water line. The instant of contact was found from a water-contact indicator on the step and the time history of the center-of-gravity displacement was determined from the times of immersion and emersion of the hull pressure gages, the fixed location of the center of gravity relative to the step, and trim-angle time history.) Integration of the time-history curve of the corrected vertical velocity from time of contact to the time of zero vertical velocity determined the maximum displacement of the center of gravity. The maximum displacements determined in this manner for all the impacts agreed within experimental error with the maximum displacements calculated from the hull pressure gages. With the use of the corrected vertical-velocity and horizontal-velocity time histories, time histories of the flight-path angle γ and the resultant velocity were computed. From the time histories of trim angle τ (fig. 4 (a)) and flight-path angle γ (fig. 4 (b)), the time history of the angle of attack α was computed (fig. 4 (c)).

With the use of the time histories of angle of attack and resultant velocity, the changes in bending moment in the wing at station 9 due to the changes in air load were determined for each impact in the manner described in the section entitled "Air-Load Variation" and are presented in parts (a) of figures 5 to 10.

FIGURE 10.—Wing-bending-moment time histories during impact; run 6.

The procedure of reference 1 was used to compute the bending moments because it provides a convenient means of applying the principles essential to a dynamic-loads analysis which results in time histories of the wing bending moments. The forcing function for each impact was determined from the normal acceleration measured in the hull by an accelerometer located near the seaplane center of gravity. Because of the manner of connection between the wing and hull (fig. 1), the measured acceleration was not appreciably affected by the oscillations of the wing. By including the effect of the varying wing lift on the center-of-gravity acceleration, the acceleration normal to the keel line due to the hydrodynamic force only was determined. From this acceleration and the mass of the seaplane, the hydrodynamic forcing function was calculated. The dynamic responses of the significant modes to this forcing function were computed by a recurrence method developed at the Langley Structures Research Division in which the actual forcing function is used without approximation. Only the dynamic effects of the fundamental bending mode were included in the final results because calculations showed the dynamic effects of the second symmetrical bending mode to be negligible. This observation was borne out by the absence of higher mode effects on the strain-gage records. The calculated time histories of the static water-load and dynamic water-load components of wing bending moment at station 9 are presented in parts (a) of figures 5 to 10. The spanwise bending-moment distribution for the fundamental-mode $1g$ inertia loading calculated as set forth in reference 1, a $1g$ static water loading, and a level-flight loading are plotted in figure 11. The values of the bending moment at station 9 used in the application of the method of reference 1 were obtained from this plot.

These three components of wing-bending-moment changes obtained in this manner for station 9 were combined and added to the wing bending moment existing at the instant of contact. This total theoretical wing bending moment is presented in parts (b) of figures 5 to 10 together with the wing-bending-moment variation measured by the strain gage at station 9.

DISCUSSION

Comparisons between the total theoretical and experimental wing bending moments are presented in parts (b) of figures 5 to 10. The comparisons are made only for wing station 9 because the bending moments in the outer wing section were so small as to be of the same order as the estimated error. Only the dynamic effects of the fundamental bending mode were included in the final results because calculations showed the dynamic effects of the second symmetrical bending mode to be negligible. This negligibility was borne out by the absence of higher-mode effects on the strain-gage records. The comparisons show the predicted values to be in good agreement with the experimental values. As can be seen from the figures, the phase relationships between the theoretical and experimental

FIGURE 11.—Level-flight and landing-impact bending moments.

values are consistently good, and the maximum changes from initial conditions show a range of error of 5 to 28 percent based on the experimental values of the maximum changes in wing moment. These results indicate that when the three components of moment are included in the theory good agreement is obtained.

A comparison of the level-flight bending moment and the change in bending moment due to the heaviest impact of the tests shows that the maximum change in bending moment accompanying a downward motion of the wing was approximately 50 percent of the level-flight moment (figs. 11 and 5 (b)). This maximum bending-moment change was produced by a $2.03g$ impact. When any differences in the response factor and any change in air-load bending moment are neglected, landings of over $4g$ would be required for the downward motion of the wing merely to start stress reversal in the wing. Similarly, even if the maximum dynamic water-load bending moment (fig. 8 (a)) caused by a $1.94g$ impact were to be twice as large for a $4g$ impact, were to exist after the water load was removed, and were to be superposed on a level-flight moment, the moment produced by the upward motion of the wing would still be less than twice the level-flight moment. Therefore, the change in bending moment due to a landing impact is unimportant in this seaplane insofar as this change will not produce critical stresses at the wing root. This unimportance may

be largely attributed to the fact that the fundamental mode $1g$ inertia loading is relatively small as compared with a level-flight loading (fig. 11).

The effects of structural flexibility on the computed bending moments can be seen by comparing the static and dynamic components of the water-load bending moment in parts (a) of figures 5 to 10 and by observing the dynamic response factors u in table III. The dynamic overstress attributable to structural flexibility is the dynamic component of stress in parts (a) of figures 5 to 10 and is represented in the response factor u by the amount that this factor differs from unity. Since response factors as high as 1.97 are obtained, the dynamic overstress sometimes contributes an increment of stress almost as large as the static water-load stress. This observation is in agreement with the results of other investigators and shows the necessity of using dynamic analyses in landing-load investigations.

The change in wing bending moment due to change in air load on the wing is a function of the changes in velocity and angle of attack. (See the section entitled "Air-Load Variation.") In these tests the changes in velocity during the impacts were small (table III) and the changes in air-load bending moment were therefore almost entirely attributable to the changes in angle of attack. Since the angle of attack is a function of the trim and flight-path angles, large changes in angle of attack will occur when the trim and flight-path angles change to a great degree. For the relatively small changes in trim angle and flight-path angle which occurred in these tests (the maximum values being 9.31° and 7.0° , respectively), air-load changes as large as $0.2g$ were computed. For this airplane, these changes in air-load bending moment were of about the same magnitude as the bending-moment changes due to the static component of loading (parts (a) of figs. 5 to 10) and inclusion of the effects of air-load changes in the calculations was therefore necessary. For other airplanes with structural and mass characteristics conducive to large inertia-load moments, the bending-moment changes accompanying a $0.2g$ change in air load would be small relative to the changes in bending moment caused by inertia loads. However, for more severe changes in flight-path angle, which should be considered in a design analysis, the effects of the change in air load on the bending moment in the wing may still be large enough to warrant consideration in a design analysis. Further investigation is necessary to determine the importance of this air-load variation in design-strength calculations.

In most landing tests the applied forcing functions are not easily obtained from the center-of-gravity accelerations because of the superposed accelerations caused by structural oscillations. But because the fuselage of this airplane is connected to the wing by struts located near the nodal point of the fundamental mode which represented the greatest portion of the wing bending and by a nonstructural fairing which neither transmitted nor interfered with the wing oscillations, the accelerometer in the fuselage was not appreciably affected by the wing oscillations in these tests.

The calculation of the dynamic response of each of the normal modes of the seaplane involves solving for the response of an equivalent simple spring-mass system to the given forcing function. In this calculation it is common practice to approximate the forcing function in order to simplify the computation. However, the responses used in this report were computed from the actual forcing functions because trial calculations showed that errors as large as 20 percent in the total response of the simple spring-mass system could be introduced by use of apparently good simple approximations.

CONCLUSIONS

Experimental wing bending moments obtained from a landing-impact investigation with a small full-scale seaplane were compared with analytical results. The effects of the variation in air load during the impacts were included in the analytical procedure. The responses of the fundamental mode were calculated from the recorded time histories of the applied hydrodynamic forces. For the seaplane tested and the conditions of the impacts encountered, the following conclusions may be drawn:

1. Good agreement between measured and computed wing bending moments was obtained when the three components of the wing moment (static water-load moment, dynamic water-load moment, and air-load moment) were included in the calculations.
2. The effects of structural flexibility on the wing bending moments, represented by the dynamic overstress and understress, were large, the moment due to the dynamic component of the total response being as much as 97 percent of that caused by the static water-load component.
3. Although the changes in seaplane attitude during the landing impacts were small, the variation in the air-load component of the total moment was of about the same magnitude as the static water-load component. Although this comparison of changes is not representative of the relative importance of the air-load variation in seaplanes with structures conducive to large inertia-load components, it indicates the probable significance of the effects of air-load variation since large changes in seaplane attitude must also be considered.

REPORT 1014

STUDY OF EFFECTS OF SWEEP ON THE FLUTTER OF CANTILEVER WINGS¹

By J. G. BARMBY, H. J. CUNNINGHAM, and I. E. GARRICK

SUMMARY

An experimental and analytical investigation of the flutter of sweptback cantilever wings is reported. The experiments employed groups of wings swept back by rotating and by shearing. The angle of sweep ranged from 0° to 60° and Mach numbers extended to approximately 0.85. A theoretical analysis of the air forces on an oscillating swept wing of high length-chord ratio is developed, and the approximations inherent in the assumptions are discussed. Comparison with experiment indicates that the analysis developed in the present report is satisfactory for giving the main effects of sweep, at least for nearly uniform cantilever wings of high and moderate length-chord ratios. A separation of the effects of finite span and compressibility in their relation to sweep has not been made experimentally but some combined effects are given. A discussion of some of the experimental and theoretical trends is given with the aid of several tables and figures.

INTRODUCTION

The present report is an outgrowth of the trend toward the use of swept wings for high-speed flight and presents the results of an analysis and of an accompanying exploratory program of research in the Langley 4.5-foot flutter research tunnel on swept cantilever wings. The material was assembled in a memorandum form with a similar title in 1948. The chief purposes of the present report are to provide a more detailed exposition of the analysis and to make the main material more generally available.

Some previous experimental and analytical work on swept wings is mentioned here. A preliminary experimental investigation of the effect of sweep on flutter has been made (reference 1) with a single, simple rigid wing mounted flexibly on a base which could be rotated to various desired sweep angles. This investigation was made at low Mach numbers for two bending-torsion frequency ratios and at several angles of sweepback. Another investigation (data unpublished) in which the density of the test medium was a variable was conducted by D. Benun on the same type of rigid, flexibly mounted wing at higher Mach numbers and at sweep angles of 0° and 45°. Other unpublished work on swept wings exists, but a search of the available information indicates a need for further systematic study.

The experimental work reported herein dealt with models mounted as cantilevers at their roots. These cantilever models differed from the rigid, flexibly mounted wings, which had all bending and torsion flexibility concentrated at the root, and thus were subject to different root effects. In order to facilitate analysis the cantilever models were uniform and untapered. The intent of the experimental program was to establish trends and to indicate orders of magnitude of the various effects of sweep on flutter rather than to isolate precisely the separate effects.

The models were swept back in two basic manners—shearing and rotating. For the case in which the wings were swept back by shearing the cross sections parallel to the air stream, the span and aspect ratio remained constant. For the other case, a series of rectangular-plan-form wings were mounted on a special base which could be rotated to provide any desired angle of sweepback. This rotatory base was also used to examine the critical speed of swept-forward wings.

Tests were conducted also on special models that were of the “rotated” type (sections normal to the leading edge were the same at all sweep angles) with the difference that the bases were aligned parallel to the air stream. Two series of such rotated models having different lengths were tested.

Inasmuch as the location of the center of gravity, the mass-density ratio, and the Mach number have important effects on the flutter characteristics of unswept wings, these parameters were varied for swept wings. In order to investigate possible changes in flutter characteristics which might be due to different flow over the tips, various tip shapes were included in the experiments.

In an analysis of flutter, vibrational characteristics are very significant; accordingly, vibration tests were made on each model. A special study of the change in frequency and mode shape with angle of sweep was made for a simple aluminum-alloy beam and is reported in appendix A.

Theoretical analyses of the effect of sweep on flutter exist only in brief or preliminary forms. In England in 1942, W. J. Duncan estimated by certain dimensional considerations the effect of sweep on the flutter speed of certain specialized wing types. Among other British workers whose names are mentioned in connection with problems

¹ Supersedes NACA TN 2121, “Study of Effects of Sweep on the Flutter of Cantilever Wings” by J. G. Barmby, H. J. Cunningham, and I. E. Garrick, 1950.

of flutter involving sweep are R. McKinnon Wood, A. R. Collar, and I. T. Minhinnick. An account of Minhinnick's work was given by Broadbent in reference 2. In reference 3 a preliminary analysis for the flutter of swept wings in incompressible flow is developed on the basis of a "strip theory" (with the strips taken in the stream direction) and is applied to the experimental results of reference 1. Examination of the limiting case of infinite span discloses that the aerodynamic assumptions employed in reference 3 are not well-grounded. Reference 4 adapts this strip theory to flexible wings and also presents an alternative "velocity component" treatment employing other aerodynamic assumptions which in their end result appear more akin to those employed in the analysis of the present report. No definite choice is made in reference 4 between the two methods although the strip-theory method is favored.

In the present report a theoretical analysis is developed anew and given a general presentation. Application of the analysis has been limited at this time chiefly to those calculations needed for comparison with experimental results. A wider examination of the effect of various parameters and of additional degrees of freedom on the flutter characteristics is desirable.

SYMBOLS

b	half-chord of wing measured perpendicular to elastic axis, feet
b_r	half-chord perpendicular to elastic axis at reference station, feet
l'	effective length of wing, measured along elastic axis, feet
c	wing chord measured perpendicular to elastic axis, inches
l	length of wing measured along midchord line, inches
Λ	angle of sweep, positive for sweepback, degrees
A_g	geometric aspect ratio $\left(\frac{l \cos \Lambda}{lc}\right)^2$
x'	coordinate perpendicular to elastic axis in plane of wing, feet
y'	coordinate along elastic axis, feet
z'	coordinate in direction perpendicular to $x'y'$ -plane, feet
Z	coordinate of wing surface in z' -direction, feet
η	nondimensional coordinate along elastic axis (y'/l')
ξ	coordinate in wind-stream direction
h	bending deflection of elastic axis, positive downward, feet
θ	torsional deflection of elastic axis, positive with leading edge up, radians
σ	local bending slope of elastic axis $\left(\frac{\partial h}{\partial y'}\right)$
τ	local rate of change of twist $\left(\frac{\partial \theta}{\partial y'}\right)$
$f_h(y'), F_h(\eta)$	deflection function of wing in bending
$f_\theta(y'), F_\theta(\eta)$	deflection function of wing in torsion
t	time
ω	angular frequency of vibration, radians per second

ω_h	angular uncoupled bending frequency, radians per second
ω_a	angular uncoupled torsional frequency about elastic axis, radians per second
f_{h_1}	first bending natural frequency, cycles per second
f_{h_2}	second bending natural frequency, cycles per second
f_t	first torsion natural frequency, cycles per second
f_a	uncoupled first torsion frequency relative to elastic axis, cycles per second $\left(f_t \left[1 - \frac{(x_a/r_a)^2}{1 - (f_{h_1}/f_t)^2}\right]^{\frac{1}{2}}\right)$
f_e	experimental flutter frequency, cycles per second
f_R	reference flutter frequency, cycles per second
f_Λ	flutter frequency determined by analysis of present report, cycles per second
v	free-stream velocity, feet per second
v_e	experimental flutter speed, feet per second
v_n	component of air-stream velocity perpendicular to elastic axis, feet per second $(v \cos \Lambda)$
V_e	experimental flutter speed taken parallel to air stream, miles per hour
V_R	reference flutter speed, miles per hour
V_R'	reference flutter speed based on wing elastic axis, miles per hour (defined in appendix B)
V_Λ	flutter speed determined by theory of present report, miles per hour
V_D	theoretical divergence speed, miles per hour
k_n	reduced frequency employing velocity component perpendicular to elastic axis $(\omega b/v_n)$
φ	phase difference between wing bending and wing torsion strains, degrees
ρ	density of testing medium at flutter, slugs per cubic foot
q	dynamic pressure at flutter, pounds per square foot
M	Mach number at flutter
M_{cr}	critical Mach number
x_{cg}	distance of center of gravity behind leading edge taken perpendicular to elastic axis, percent chord
x_{ea}	distance of elastic center of wing cross section behind leading edge taken perpendicular to elastic axis, percent chord
x_{ea}'	distance of elastic axis of wing behind leading edge taken perpendicular to elastic axis, percent chord
a	nondimensional elastic-axis position $\left(\frac{2x_{ea}}{100} - 1\right)$
$a + x_a$	nondimensional center-of-gravity position $\left(\frac{2x_{cg}}{100} - 1\right)$
m	mass of wing per unit length, slugs per foot
κ	wing mass-density ratio at flutter $(\pi \rho b^2/m)$
I_a	mass moment of inertia of wing per unit length about elastic axis, slug-feet ² per foot

r_α	nondimensional radius of gyration of wing about elastic axis $\left(\sqrt{\frac{I_\alpha}{m b^2}}\right)$
EI	bending stiffness, pound-inches ² in tables, pound-feet ² in analysis
GJ	torsional stiffness, pound-inches ² in tables, pound-feet ² in analysis
g_h	structural damping coefficient for bending vibration
g_α	structural damping coefficient for torsional vibration
P	oscillatory lift per unit length, positive downward (defined in equation (6))
M_α	oscillatory moment about elastic axis, positive leading edge up (defined in equation (7))
[]	a special bracket used to identify terms which are due solely to inclusion of the last term in equation (5b)

In order to preserve continuity and to facilitate comparison with previous work on the unswept wing, the subscript α rather than θ is retained with certain quantities to refer to the torsional degree of freedom.

ANALYTICAL INVESTIGATION

GENERAL

Assumptions.—An attempt is first made to point out the main assumptions which seem to be applicable for swept wings of moderate taper and of high or moderate length-chord ratios.

(a) The assumptions, such as small disturbances and potential flow, commonly employed in linearized treatment of unswept wings in an ideal incompressible fluid are made.

(b) The structural behavior is such that over the main part of the wing the elastic axis may be considered straight. The wing is also considered sufficiently stiff at the root so that it behaves as if it were clamped normal to the elastic axis. An effective length l' needed for integration reasons may be defined (for example, as in fig. 1). The angle of sweepback is measured in the plane of the wing from the direction normal to the air stream to the elastic axis. All section parameters such as semichord, locations of elastic axis and center of gravity, radius of gyration, and so forth, are based on sections normal to the elastic axis.

FIGURE 1.—Nonuniform swept wing treated in the present analysis.

(c) The aerodynamic behavior is such that any section dy' of the wing normal to the elastic axis, taken in the direction of the component $v \cos \Lambda$ of the main-stream velocity, generates a velocity potential associated with a uniform infinite swept wing having the same instantaneous distribution over the chord of velocity normal to the wing surface as does the actual section.

Additional remarks on these assumptions are appropriate. With regard to assumption (a), in accordance with linearization of the problem, the boundary conditions are stated and treated with respect to a reference surface, in this case a plane, containing the mean equilibrium position of the wing and the main-stream velocity. Furthermore, incompressible flow is assumed in order to avoid complexity of the analysis, although modifications due to Mach number effects can be added. Such modifications may be based, for example, for wings having large length-chord ratios, on existing theoretical calculations of aerodynamic coefficients for subsonic or supersonic two-dimensional flow appropriate to the component $v \cos \Lambda$. On the other hand the modifications may be partly empirical, especially for "transonic" conditions and for small length-chord ratios. The transonic conditions and the general aerodynamic behavior of swept wings may depend, for large length chord ratios, on the component $v \cos \Lambda$, but the dependence may shift to the stream velocity v for small length-chord ratios.

With respect to assumption (b), results of analyses of and experiment on unswept wings having low ratios of bending frequency to torsion frequency show that small variations of position of the elastic axis are not important. The assumption of a straight elastic axis over the main part of a swept wing, similarly, is not critical for many cases. This assumption is made for convenience, however, and modifications for a curved elastic axis can be made when necessary, for example, for plate-like wings. Small differences in the angle of sweepback of the leading edge, quarter-chord line, elastic axis, and so forth, are neglected. The analysis could be further modified to take into account variation of the angle of sweepback along the length of the wing.

Assumption (c) implies that associated with the action of the wing in pushing air downward there is a noncirculatory potential-type flow similar to that around sections of an infinite flat-plate wing. Furthermore, as in the case of the unswept airfoil, a circulatory potential-type flow is generated in which for the swept airfoil the component $v \cos \Lambda$ is decisive in fixing the circulation. (This assumption differs from that made in the strip theory of references 3 and 4 which employs the main-stream velocity together with sections of the wings parallel to the stream direction.) Effects of the floating of the wake in the stream direction rather than in the direction of $v \cos \Lambda$ and induced effects of variation of the strength of the wake in the wing-length direction are neglected, as are three-dimensional tip effects. For large values of the reduced frequency k_n , a given segment of the wing might be influenced chiefly by the nearby wake and the correction would be small. On the other hand, for small values of k_n a given segment might be influenced by a more widespread portion of the wake; corrections for this condition may possibly be based on knowledge of the static

case (for example, slope of the lift curve). As the angle of sweep approaches 90° , obviously the mechanism for the generation of lift is different from the one postulated here; for example, a tip condition may replace the trailing-edge condition and considerations of very small aspect ratio arise.

Basic considerations.—Consider the configuration shown in figure 1 where the vertical coordinate of the wing surface is denoted by $z' = Z(x', y', t)$ (positive downward). The effect of the position and motion of the wing may be given by the disturbance-velocity distribution to be superposed on the uniform stream in order to represent the condition of tangential flow at the wing surface. This velocity distribution normal to the surface (positive upward) is, for small disturbances,

$$w(x', y', t) = \frac{\partial Z}{\partial t} + v \frac{\partial Z}{\partial \xi} \quad (1a)$$

where ξ is the coordinate in the wind-stream direction. With the use of the relation

$$\begin{aligned} \frac{\partial Z}{\partial \xi} &= \frac{\partial Z}{\partial x'} \frac{\partial x'}{\partial \xi} + \frac{\partial Z}{\partial y'} \frac{\partial y'}{\partial \xi} \\ &= \frac{\partial Z}{\partial x'} \cos \Lambda + \frac{\partial Z}{\partial y'} \sin \Lambda \end{aligned}$$

the vertical velocity at any point is

$$w(x', y', t) = \frac{\partial Z}{\partial t} + v \frac{\partial Z}{\partial x'} \cos \Lambda + v \frac{\partial Z}{\partial y'} \sin \Lambda \quad (1b)$$

Let the wing be bending so that a segment dy' (see fig. 1) is displaced from its equilibrium position by an incremental distance h (positive down) and also let the wing segment be twisting about the elastic axis through an incremental angle θ (positive leading edge up). The position of each point of the segment may be defined, for small deflections, by

$$Z = h + x'\theta \quad (2)$$

The velocity distribution normal to the surface, equation (1b), consequently becomes

$$w = \dot{h} + x'\dot{\theta} + v\theta \cos \Lambda + v(\sigma + x'\tau) \sin \Lambda \quad (3)$$

where $\sigma = \frac{\partial h}{\partial y'}$ is the local bending slope of the elastic axis and is thus analogous to dihedral, and where $\tau = \frac{\partial \theta}{\partial y'}$ is the local change of twist of the elastic axis.

In accordance with assumption (c) the noncirculatory-flow velocity potentials associated with the vertical-velocity distribution are first needed. In equation (3) the terms involving $\dot{h}$, $\dot{\theta}$, and σ are constant across the chord, whereas those

involving θ and τ vary in a linear manner. The noncirculatory velocity potentials as in reference 5 and the new potentials associated with σ and τ are

$$\left. \begin{aligned} \phi_h &= \dot{h} b \sqrt{1-x^2} \\ \phi_\theta &= v_n \theta b \sqrt{1-x^2} \\ \phi_\sigma &= v_n \sigma \tan \Lambda b \sqrt{1-x^2} \\ \phi_\theta &= \theta b^2 \left(\frac{x}{2} - a \right) \sqrt{1-x^2} \\ \phi_\tau &= v_n \tau \tan \Lambda b^2 \left(\frac{x}{2} - a \right) \sqrt{1-x^2} \end{aligned} \right\} \quad (4)$$

where $v_n = v \cos \Lambda$ and x is the nondimensional chordwise coordinate measured from the midchord as in reference 5 and related to the coordinate x' in the manner

$$x = \frac{x'}{b} + a$$

The velocity potential for the circulatory flow associated with the wake may be developed on the basis of assumption (c) and the concepts for the infinite unswept wing introduced in reference 5. (Thus the circulatory-flow pattern for a section dy' of the finite swept wing is to be obtained from the corresponding flow pattern for an infinite uniform yawed wing. This infinite wing is assumed to have undergone harmonic oscillations for a long time; the full wake is established, remains where formed, and consequently is harmonically distributed in space. For the infinite uniform yawed wing, results for the circulatory flow are like those of reference 5 with v replaced by the component v_n and with the addition of terms to take care of σ and τ .) In particular, the strength of the wake acting on each section is determined by the condition of smooth flow (the velocity remaining finite) at the trailing edge. This condition is utilized in the form $\frac{\partial}{\partial x} (\phi_r + \phi_N)$

is equal to a finite quantity at the trailing edge (where ϕ_r is the velocity potential due to the vorticity in the wake, and ϕ_N is the total noncirculatory velocity potential), and this condition leads to a relation analogous to equation (VII) of reference 5 involving the basic quantity

$$Q = \dot{h} + v_n \dot{\theta} + v_n \sigma \tan \Lambda + b \left(\frac{1}{2} - a \right) (\dot{\theta} + v_n \tau \tan \Lambda)$$

which occurs in the terms associated with the wake. The net result of these considerations is that the circulatory-flow velocity potential may be regarded as determined.

The pressure difference between upper and lower surfaces of the wing at a point x is (positive downward)

$$\begin{aligned} p &= -2\rho \left(\frac{\partial \phi}{\partial t} + v \frac{\partial \phi}{\partial \xi} \right) \\ &= -2\rho \left(\frac{\partial \phi}{\partial t} + v \frac{\partial \phi}{\partial x'} \cos \Lambda + v \frac{\partial \phi}{\partial y'} \sin \Lambda \right) \end{aligned} \quad (5a)$$

where ϕ is in general the total potential (the sum of circulatory-flow and noncirculatory-flow potentials). The last term in equation (5a) is the product of the component of main-stream velocity taken along the wing and the lengthwise change in the velocity potential and is often neglected even in steady-flow work. The question of the retention or neglect of this last term seems partly dependent on the order in which the approximations are introduced—specifically, whether velocity potentials for the whole flow pattern are found and then the integrated forces are determined or whether section forces are first determined and then integrated. It seems appropriate to retain at least the noncirculatory part ϕ_N of ϕ in the last term of equation (5a). In view, however, of the nature of the approximate treatment of the circulatory potential and of the inherent shortcomings of a strip analysis, in particular the neglect of lengthwise variations in wake vortex strength, complicating the results by also including ϕ_r in this term does not appear worth while. (This neglect of ϕ_r and retention of ϕ_N is realized to involve some inconsistencies in that account may not be taken of other higher order terms associated with lengthwise variation of the wing wake, which may be of the same order as terms retained.) Thus equation (5a) becomes

$$p = -2\rho \left(\frac{\partial \phi}{\partial t} + v \frac{\partial \phi}{\partial x'} \cos \Lambda + v \frac{\partial \phi_N}{\partial y'} \sin \Lambda \right) \quad (5b)$$

For harmonic motion in each degree of freedom, relations for the pressure may be integrated over the chord to yield expressions for the air forces and moments. For the sake of separating and identifying the terms in force and moment expressions which are due solely to the inclusion of the last term in equation (5b), a special bracket [] is employed. Thus these terms may be readily omitted. Numerical checks among the calculations made for the present report showed the effect of inclusion of the last term in equation (5b) on the calculated results to be quite small, even for 60° of sweepback within the range of other parameters investigated.

The expressions for the aerodynamic lift (positive down) and for the moment about the elastic axis (positive leading edge up), each per unit length of the wing, are as follows:

$$\begin{aligned} P &= -2\pi\rho v_n b C \left[\dot{h} + v_n \dot{\theta} + v_n \dot{\sigma} \tan \Lambda + b \left(\frac{1}{2} - a \right) (\dot{\theta} + v_n \dot{\tau} \tan \Lambda) \right] - \\ &\quad \pi\rho b^2 \left[\ddot{h} + v_n \ddot{\theta} + v_n \ddot{\sigma} \tan \Lambda + \{ v_n \ddot{\sigma} \tan \Lambda + v_n^2 \dot{\tau} \tan \Lambda + v_n^2 \frac{\partial \sigma}{\partial y'} \tan^2 \Lambda \} \right] + \\ &\quad \pi\rho b^3 a \left[\ddot{\theta} + v_n \ddot{\tau} \tan \Lambda + \left\{ v_n \ddot{\tau} \tan \Lambda + v_n^2 \frac{\partial \tau}{\partial y'} \tan^2 \Lambda \right\} \right] \end{aligned} \quad (6)$$

$$\begin{aligned} M_a &= 2\pi\rho v_n b^2 \left(\frac{1}{2} + a \right) C \left[\dot{h} + v_n \dot{\theta} + v_n \dot{\sigma} \tan \Lambda + b \left(\frac{1}{2} - a \right) (\dot{\theta} + v_n \dot{\tau} \tan \Lambda) \right] - \\ &\quad \pi\rho v_n b^3 \left[\left(\frac{1}{2} - a \right) \ddot{\theta} + \frac{1}{2} v_n \ddot{\tau} \tan \Lambda \right] + \pi\rho b^3 a \left[\ddot{h} + v_n \ddot{\sigma} \tan \Lambda + \right. \\ &\quad \left. \left\{ v_n \ddot{\sigma} \tan \Lambda + v_n^2 \dot{\tau} \tan \Lambda + v_n^2 \frac{\partial \sigma}{\partial y'} \tan^2 \Lambda \right\} \right] - \pi\rho b^4 \left(\frac{1}{8} + a^2 \right) \left[\ddot{\theta} + \right. \\ &\quad \left. v_n \ddot{\tau} \tan \Lambda + \left\{ v_n \ddot{\tau} \tan \Lambda + v_n^2 \frac{\partial \tau}{\partial y'} \tan^2 \Lambda \right\} \right] \end{aligned} \quad (7)$$

where

$$C = C(k_n) = F(k_n) + iG(k_n)$$

is the function associated with the wake developed by Theodorsen in reference 5; the reduced frequency parameter k_n is defined by

$$k_n = \frac{\omega b}{v_n} = \frac{\omega b}{v \cos \Lambda} \quad (8)$$

As has already been stated, the foregoing expressions were developed and apply for steady sinusoidal oscillations,

$$\left. \begin{aligned} h &= h_1(y') e^{i\omega t} \\ \theta &= \theta_1(y') e^{i\omega t} \end{aligned} \right\} \quad (9)$$

The amplitude, velocity, and acceleration in each degree of freedom are related as in the degree of freedom h ; that is,

$$\dot{h} = i\omega h$$

$$\ddot{h} = -\omega^2 h$$

Expressions for force and moment.—With the use of such relations, equations (6) and (7) may be put into the form

$$P = -\pi \rho b^3 \omega^2 (h B_{ch} + \theta B_{c\theta}) \quad (10a)$$

$$M_a = -\pi \rho b^4 \omega^2 (h B_{ah} + \theta B_{a\theta}) \quad (11a)$$

where

$$B_{ch} = \frac{1}{b} A_{ch} + \frac{\sigma}{h} \tan \Lambda \left(-i \frac{1}{k_n} \right) ([-1] + A_{ch}) + \left\{ \frac{b}{h} \frac{\partial \sigma}{\partial y'} \tan^2 \Lambda \left(\frac{1}{k_n^2} \right) \right\}$$

$$B_{c\theta} = A_{c\alpha} + \frac{\tau}{\theta} b \tan \Lambda (A_{c\tau}) + \left\{ \frac{b^2}{\theta} \frac{\partial \tau}{\partial y'} \tan^2 \Lambda \left(-\frac{a}{k_n^2} \right) \right\}$$

$$B_{ah} = \frac{1}{b} A_{ah} + \frac{\sigma}{h} \tan \Lambda \left(-i \frac{1}{k_n} \right) ([a] + A_{ah}) + \left\{ \frac{b}{h} \frac{\partial \sigma}{\partial y'} \tan^2 \Lambda \left(-\frac{a}{k_n^2} \right) \right\}$$

$$B_{a\theta} = A_{a\alpha} + \frac{\tau}{\theta} b \tan \Lambda (A_{a\tau}) + \left\{ \frac{b^2}{\theta} \frac{\partial \tau}{\partial y'} \tan^2 \Lambda \left(\frac{1}{8} + a^2 \right) \frac{1}{k_n^2} \right\}$$

in which the four following coefficients:

$$A_{ch} = -1 - \frac{2G}{k_n} + i \frac{2F}{k_n}$$

$$A_{c\alpha} = a + \frac{2F}{k_n^2} - \left(\frac{1}{2} - a \right) \frac{2G}{k_n} + i \left[\frac{1}{k_n} + \frac{2G}{k_n^2} + \left(\frac{1}{2} - a \right) \frac{2F}{k_n} \right]$$

$$\begin{aligned} A_{ah} &= a + \left(\frac{1}{2} + a \right) \frac{2G}{k_n} + i \left(\frac{1}{2} + a \right) \left(-\frac{2F}{k_n} \right) \\ &= -\frac{1}{2} - \left(\frac{1}{2} + a \right) A_{ch} \end{aligned}$$

$$\begin{aligned} A_{a\alpha} &= -\frac{1}{8} - a^2 - \left(\frac{1}{2} + a \right) \frac{2F}{k_n^2} + \left(\frac{1}{4} - a^2 \right) \frac{2G}{k_n} + \\ &+ i \left[\left(\frac{1}{2} - a \right) \frac{1}{k_n} - \left(\frac{1}{4} - a^2 \right) \frac{2F}{k_n} - \left(\frac{1}{2} + a \right) \frac{2G}{k_n^2} \right] \end{aligned}$$

are identical with those used in the case of the unswept wing. Additionally,

$$A_{c\tau} = \left\{ \frac{1}{k_n^2} \right\} - i \frac{1}{k_n} \left[\frac{1}{2} + [a] + \left(\frac{1}{2} - a \right) A_{ch} \right]$$

$$A_{a\tau} = -i \frac{1}{k_n} \left[-\left(\frac{3}{8} + \left\{ \frac{1}{8} + a^2 \right\} \right) + i \frac{1}{k_n} \left(\frac{1}{2} - [a] \right) - \left(\frac{1}{4} - a^2 \right) A_{ch} \right]$$

It is of interest to note that equations (6) and (7) reduce, for the case of the wing in steady flow ($k_n = 0$), to

$$\begin{aligned} P &= -2\pi \rho b v_n^2 \left[\theta + \sigma \tan \Lambda + \tau b \tan \Lambda \left(\left\{ \frac{1}{2} \right\} + \frac{1}{2} - a \right) + \right. \\ &\quad \left. \left\{ \frac{b}{2} \frac{\partial \sigma}{\partial y'} \tan^2 \Lambda - \frac{a}{2} b^2 \frac{\partial \tau}{\partial y'} \tan^2 \Lambda \right\} \right] \quad (10b) \end{aligned}$$

$$\begin{aligned} M_a &= 2\pi \rho b^2 v_n^2 \left[(\theta + \sigma \tan \Lambda) \left(\frac{1}{2} + a \right) + \tau a b \tan \Lambda \left(\left\{ \frac{1}{2} \right\} - a \right) + \right. \\ &\quad \left. \left\{ \frac{a b}{2} \frac{\partial \sigma}{\partial y'} \tan^2 \Lambda - \frac{1}{2} b^2 \left(\frac{1}{8} + a^2 \right) \frac{\partial \tau}{\partial y'} \tan^2 \Lambda \right\} \right] \quad (11b) \end{aligned}$$

per unit length of wing.

Introduction of modes.—Equations (10a) and (11a) give the total aerodynamic force and moment on a segment of a sweptback wing oscillating in a simple harmonic manner. Relations for mechanical equilibrium applicable to a wing segment may be set up, but it is preferable to bring in directly the three-dimensional-mode considerations. (See for example, reference 6.) This end may be readily accomplished by the combined use of Rayleigh type approximations and the classical methods of Lagrange. The vibrations at flutter are assumed to consist of a combination of fixed mode shapes, each mode shape representing a degree of freedom associated with a generalized coordinate. The total mechanical energy, the potential energy, and the work done by applied forces, aerodynamic and structural, are then obtained by the integration of the section characteristics over the span. The Rayleigh type approximation enters in the representation of the potential energy in terms of the uncoupled frequencies.

As is customary, the modes are introduced into the problem as varying sinusoidally with time. For the purpose of simplicity of analysis, one bending degree of freedom and one torsion degree of freedom are carried through in the present development. Actually, any number of degrees of freedom may be added if desired, exactly as with an unswept wing. Let the mode shapes be represented by

$$\left. \begin{aligned} h &= [f_h(y')] \underline{h} \\ \theta &= [f_\theta(y')] \underline{\theta} \end{aligned} \right\} \quad (12)$$

where $h = h_o e^{i\omega t}$ is the generalized coordinate in the bending degree of freedom, and $\theta = \theta_o e^{i\omega t}$ is the generalized coordinate in the torsion degree of freedom. (In a more general treatment the mode shapes must be solved, but in this procedure $f_h(y')$ and $f_\theta(y')$ are chosen, ordinarily as real functions of y' . Complex functions may be used to represent twisted modes.) The constants h_o and θ_o are in general complex and thus signify the phase difference between the two degrees of freedom.

In the subsequent treatment the reader will notice that in some expressions, namely for force and moment, h and θ can conveniently and logically be retained in their complex form. In other expressions, notably for energy, one is forced to utilize h and θ as real quantities. Appropriate statements will be made where necessary.

For each degree of freedom an equation of equilibrium may be obtained from Lagrange's equation

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{q}_i} \right) - \frac{\partial T}{\partial q_i} + \frac{\partial U}{\partial q_i} = Q_i \quad (13)$$

where q_i is a generalized coordinate and Q_i is the corresponding generalized force. The kinetic energy of the mechanical system is

$$T = \frac{1}{2} \dot{h}^2 \int_0^{l'} m [f_h(y')]^2 dy' + \frac{1}{2} \dot{\theta}^2 \int_0^{l'} I_a [f_\theta(y')]^2 dy' + \dot{h} \dot{\theta} \int_0^{l'} m x_a b [f_h(y')] [f_\theta(y')] dy' \quad (14)$$

where h and θ here and in the subsequent equations (15) are to be interpreted as real in order that the energy be always positive (or zero), and for definiteness can be regarded as the real parts of $h_0 e^{i\omega t}$ and $\theta_0 e^{i\omega t}$ respectively; and where

m mass of wing per unit length, slugs per foot
 I_a mass moment of inertia of wing about its elastic axis per unit length, slug-feet² per foot
 $x_a b$ distance of sectional center of gravity from the elastic axis, positive rearward, feet

The potential energy of the mechanical system may be expressed in a form not involving bending-torsion cross-stiffness terms:

$$U = \frac{1}{2} h^2 \int_0^{l'} EI \left(\frac{d^2 f_h}{dy'^2} \right)^2 dy' + \frac{1}{2} \theta^2 \int_0^{l'} GJ \left(\frac{df_\theta}{dy'} \right)^2 dy' \quad (15a)$$

where

EI bending stiffness, pound-feet²
 GJ torsional stiffness, pound-feet²

If Rayleigh type approximations are used to introduce frequency, the expression for the potential energy may be written in a more convenient form:

$$U = \frac{1}{2} \omega_h^2 h^2 \int_0^{l'} m f_h^2 dy' + \frac{1}{2} \omega_a^2 \theta^2 \int_0^{l'} I_a f_\theta^2 dy' \quad (15b)$$

Another expression for the potential energy is

$$U = \frac{1}{2} h^2 \int_0^{l'} C_h f_h^2 dy' + \frac{1}{2} \theta^2 \int_0^{l'} C_a f_\theta^2 dy' \quad (15c)$$

The effective spring constants C_h and C_a correspond to unit length of wing and thus conform to their use in references 5 to 7. The constants are effectively defined by

$$\omega_h^2 = \frac{\int_0^{l'} C_h f_h^2 dy'}{\int_0^{l'} m f_h^2 dy'} \quad \omega_a^2 = \frac{\int_0^{l'} C_a f_\theta^2 dy'}{\int_0^{l'} I_a f_\theta^2 dy'}$$

These effective spring constants are related to the frequencies associated with the chosen modes. For so-called uncoupled

modes the frequencies appropriate to pure modes (obtained by proper constraints) are often used. On the other hand, employment of the normal or natural modes and frequencies appropriate to them, which might be obtained by proper ground test or by calculation, may be preferred. In either case the convenience of not having cross-stiffness terms in the potential-energy expression is noted.

Application is now made to obtain the equation of equilibrium in the bending degree of freedom. Equation (13) becomes

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{h}} \right) - \frac{\partial T}{\partial h} + \frac{\partial U}{\partial h} = Q_h \quad (16)$$

The term Q_h represents all the bending forces not derivable from the potential-energy function and consists of the aerodynamic forces together with the structural damping forces. The virtual work δW done on the wing by these forces as the wing moves through the virtual displacements δh and $\delta \theta$ is

$$\begin{aligned} \delta W &= \int_0^{l'} \left[\left(P - C_h \frac{g_h}{\omega} \dot{h} \right) \delta h + \left(M_a - C_a \frac{g_a}{\omega} \dot{\theta} \right) \delta \theta \right] dy' \\ &= \int_0^{l'} \left(P - m \omega_h^2 \frac{g_h}{\omega} f_h \dot{h} \right) f_h dy' \delta h + \\ &\quad \int_0^{l'} \left(M_a - I_a \omega_a^2 \frac{g_a}{\omega} f_\theta \dot{\theta} \right) f_\theta dy' \delta \theta = Q_h \delta h + Q_\theta \delta \theta \end{aligned} \quad (17)$$

where

g_h structural damping coefficient for bending vibration
 g_a structural damping coefficient for torsional vibration

In this expression the aerodynamic forces appropriate to sinusoidal oscillations are used. The application of the structural damping as in equation (17) (proportional to deflection and in phase with velocity) corresponds to the manner in which it is introduced in reference 7. In accordance with the preceding development, the aerodynamic and structural damping forces and moments in equation (17) are regarded as complex, but the virtual displacements δh and $\delta \theta$ should be considered real. Thus, the physically significant part of the resulting expression for virtual work is the real part. Since the subsequent analysis reverts to expressions for forces and moments, no further qualifications on the use of h and θ in their convenient complex forms are needed.

For the half-wing

$$\begin{aligned} Q_h &= \int_0^{l'} \left(P - m \omega_h^2 \frac{g_h}{\omega} f_h \dot{h} \right) f_h dy' \\ &= -\pi \rho b r^3 \omega^2 \int_0^{l'} \left(\frac{b}{b_r} \right)^3 \left[\frac{h}{b} A_{ch} f_h^2 + \frac{h}{b} \left(-i \frac{1}{k_n} \right) ([-1] + \right. \\ &\quad \left. A_{ch}) (\tan \Lambda) f_h \frac{df_h}{dy'} + \left\{ \frac{h}{b} \frac{1}{k_n^2} b (\tan^2 \Lambda) f_h \frac{d^2 f_h}{dy'^2} \right\} + \right. \\ &\quad \left. \theta A_{ca} f_\theta f_h + \theta A_{ca} b (\tan \Lambda) f_h \frac{df_\theta}{dy'} + \right. \\ &\quad \left. \left\{ \theta \left(-\frac{a}{k_n^2} \right) b^2 (\tan^2 \Lambda) f_h \frac{d^2 f_\theta}{dy'^2} \right\} + \frac{h}{b} \frac{1}{k_n} i \left(\frac{\omega_h}{\omega} \right)^2 g_h f_h^2 \right] dy' \end{aligned} \quad (18)$$

where b_r is the semichord at some reference section. Performance of the operations indicated in equation (16) and collection of terms lead to the equation of equilibrium in the bending degree of freedom

$$\begin{aligned} & \left(\underline{h} \left[1 - \left(\frac{\omega}{\omega_n} \right)^2 (1 + i g_n) \right] \frac{l'}{b_r} \int_0^{l'} \left(\frac{b}{b_r} \right)^2 \frac{1}{\kappa} f_h^2 dy' - \frac{1}{b_r} \int_0^{l'} \left(\frac{b}{b_r} \right)^2 A_{ch} f_h^2 dy' + \int_0^{l'} \left(\frac{b}{b_r} \right)^3 \tan \Lambda \left(i \frac{1}{k_n} \right) ([1] + A_{ch}) f_h \frac{df_h}{dy'} dy' - \left[b_r \int_0^{l'} \left(\frac{b}{b_r} \right)^4 \tan^2 \Lambda \left(\frac{1}{k_n^2} \right) f_h \frac{d^2 f_h}{dy'^2} dy' \right] \right) + \underline{\theta} \left\{ \int_0^{l'} \left(\frac{b}{b_r} \right)^3 \left(\frac{x_\alpha}{\kappa} - A_{ca} \right) f_h f_\theta dy' - b_r \int_0^{l'} \left(\frac{b}{b_r} \right)^4 A_{cr} (\tan \Lambda) f_h \frac{df_\theta}{dy'} dy' + \left[b_r^2 \int_0^{l'} \left(\frac{b}{b_r} \right)^5 \frac{a}{k_n^2} \tan^2 \Lambda f_h \frac{d^2 f_\theta}{dy'^2} dy' \right] \right\} \pi \rho b_r^3 \omega^2 = 0 \end{aligned} \quad (19a)$$

where

$$\frac{1}{\kappa} = \frac{m}{\pi \rho b^2}$$

By a parallel development the equation of equilibrium for the torsional degree of freedom may also be obtained as follows:

$$\begin{aligned} & \left(\underline{h} \left\{ \frac{1}{b_r} \int_0^{l'} \left(\frac{b}{b_r} \right)^3 \left(\frac{x_\alpha}{\kappa} - A_{ah} \right) f_h f_\theta dy' + \int_0^{l'} \left(\frac{b}{b_r} \right)^4 \tan \Lambda \left(i \frac{1}{k_n} \right) ([a] + A_{ah}) f_\theta \frac{df_h}{dy'} dy' + \left[b_r \int_0^{l'} \left(\frac{b}{b_r} \right)^5 \tan^2 \Lambda \left(\frac{a}{k_n^2} \right) f_\theta \frac{d^2 f_h}{dy'^2} dy' \right] \right\} + \underline{\theta} \left\{ \left[1 - \left(\frac{\omega}{\omega_n} \right)^2 (1 + i g_n) \right] \int_0^{l'} \left(\frac{b}{b_r} \right)^4 \frac{r_\alpha^2}{\kappa} f_\theta^2 dy' - \int_0^{l'} \left(\frac{b}{b_r} \right)^4 A_{aa} f_\theta^2 dy' - b_r \int_0^{l'} \left(\frac{b}{b_r} \right)^5 \tan \Lambda (A_{ar}) f_\theta \frac{df_\theta}{dy'} dy' - \left[b_r^2 \int_0^{l'} \left(\frac{b}{b_r} \right)^6 \tan^2 \Lambda \left(\frac{1}{8} + a^2 \right) \frac{1}{k_n^2} f_\theta \frac{d^2 f_\theta}{dy'^2} dy' \right] \right\} \right) \pi \rho b_r^4 \omega^2 = 0 \end{aligned} \quad (20a)$$

where $r_\alpha = \sqrt{I_\alpha / m b^2}$ (radius of gyration of wing about the elastic axis).

Determinantal equation for flutter.—Equations (19a) and (20a) may be rewritten with the use of the nondimensional coordinate $\eta = \frac{y'}{l'}$. They then are in the form

$$(\underline{h} A_2 + \underline{\theta} B_2) \pi \rho b_r^3 \omega^2 = 0 \quad (19b)$$

$$(\underline{h} D_2 + \underline{\theta} E_2) \pi \rho b_r^4 \omega^2 = 0 \quad (20b)$$

where

$$\begin{aligned} A_2 &= \left[1 - \left(\frac{\omega}{\omega_n} \right)^2 (1 + i g_n) \right] \frac{l'}{b_r} \int_0^{1.0} \left(\frac{b}{b_r} \right)^2 \frac{1}{\kappa} [F_h(\eta)]^2 d\eta - \frac{l'}{b_r} \int_0^{1.0} \left(\frac{b}{b_r} \right)^2 A_{ch} [F_h(\eta)]^2 d\eta + \\ & \quad \int_0^{1.0} \left(\frac{b}{b_r} \right)^3 \tan \Lambda \left(i \frac{1}{k_n} \right) ([1] + A_{ch}) [F_h(\eta)] \frac{dF_h}{d\eta} d\eta - \left[\frac{b_r}{l'} \int_0^{1.0} \left(\frac{b}{b_r} \right)^4 \tan^2 \Lambda \left(\frac{1}{k_n^2} \right) [F_h(\eta)] \frac{d^2 F_h}{d\eta^2} d\eta \right] \\ B_2 &= l' \int_0^{1.0} \left(\frac{b}{b_r} \right)^3 \left(\frac{x_\alpha}{\kappa} - A_{ca} \right) [F_h(\eta)] [F_\theta(\eta)] d\eta - b_r \int_0^{1.0} \left(\frac{b}{b_r} \right)^4 \tan \Lambda (A_{cr}) [F_h(\eta)] \frac{dF_\theta}{d\eta} d\eta + \\ & \quad \left[\frac{b_r^2}{l'} \int_0^{1.0} \left(\frac{b}{b_r} \right)^5 \tan^2 \Lambda \left(\frac{a}{k_n^2} \right) [F_h(\eta)] \frac{d^2 F_\theta}{d\eta^2} d\eta \right] \\ D_2 &= \frac{l'}{b_r} \int_0^{1.0} \left(\frac{b}{b_r} \right)^3 \left(\frac{x_\alpha}{\kappa} - A_{ah} \right) [F_\theta(\eta)] [F_h(\eta)] d\eta + \int_0^{1.0} \left(\frac{b}{b_r} \right)^4 \tan \Lambda \left(i \frac{1}{k_n} \right) ([a] + A_{ah}) [F_\theta(\eta)] \frac{dF_h}{d\eta} d\eta + \\ & \quad \left[\frac{b_r}{l'} \int_0^{1.0} \left(\frac{b}{b_r} \right)^5 \tan^2 \Lambda \left(\frac{a}{k_n^2} \right) [F_\theta(\eta)] \frac{d^2 F_h}{d\eta^2} d\eta \right] \\ E_2 &= l' \left[1 - \left(\frac{\omega}{\omega_n} \right)^2 (1 + i g_n) \right] \int_0^{1.0} \left(\frac{b}{b_r} \right)^4 \frac{r_\alpha^2}{\kappa} [F_\theta(\eta)]^2 d\eta - l' \int_0^{1.0} \left(\frac{b}{b_r} \right)^4 A_{aa} [F_\theta(\eta)]^2 d\eta - \\ & \quad b_r \int_0^{1.0} \left(\frac{b}{b_r} \right)^5 \tan \Lambda (A_{ar}) [F_\theta(\eta)] \frac{dF_\theta}{d\eta} d\eta - \left[\frac{b_r^2}{l'} \int_0^{1.0} \left(\frac{b}{b_r} \right)^6 \tan^2 \Lambda \left(\frac{1}{8} + a^2 \right) \frac{1}{k_n^2} [F_\theta(\eta)] \frac{d^2 F_\theta}{d\eta^2} d\eta \right] \end{aligned}$$

in which $F_h(\eta) = f_h(l'\eta)$ and $F_\theta(\eta) = f_\theta(l'\eta)$.

The borderline condition of flutter, separating damped and undamped oscillations, is determined from the nontrivial solution of the simultaneous homogeneous equations (19b) and (20b). Such a solution corresponds to the fact that mechan-

ical equilibrium exists for sinusoidal oscillations at a certain airspeed and with a certain frequency. The flutter condition thus is given by the vanishing of the determinant of the coefficients

$$\begin{vmatrix} A_2 & B_2 \\ D_2 & E_2 \end{vmatrix} = 0$$

Application to the case of uniform, cantilever swept wings is made in the next section.

APPLICATION TO UNIFORM CANTILEVER SWEPT WINGS

The first step in the application of the theory is to assume or develop the deflection functions to be used. For the purpose of applying the analysis to the wing models employed in the experiments it appeared reasonable to use for the deflection functions, $F_h(\eta)$ and $F_\theta(\eta)$, the uncoupled first bending and first torsion mode shapes of an ideal uniform cantilever beam. Although approximations for these mode shapes could be used, the analysis utilized the exact expressions developed from equations (120) and (106d), respectively, of reference 8 by application of appropriate boundary conditions.

The bending-mode shape can be written

$$F_h(\eta) = C_1 \left[\frac{\sinh \beta_1 + \sin \beta_1}{\cosh \beta_1 + \cos \beta_1} (\cos \beta_1 \eta - \cosh \beta_1 \eta) + \sinh \beta_1 \eta - \sin \beta_1 \eta \right]$$

where $\beta_1 = 0.5969\pi$ for first bending. The torsion mode shape can be written

$$F_\theta(\eta) = C_2 \sin \beta_2 \eta$$

where $\beta_2 = \frac{\pi}{2}$ for first torsion and C_1 and C_2 are constants.

The integrals appearing in the determinant elements A_2 , B_2 , D_2 , and E_2 are

$$\begin{aligned} \int_0^{1.0} F_h^2 d\eta &= 1.8554 C_1^2 \\ \int_0^{1.0} F_\theta^2 d\eta &= 0.5000 C_2^2 \\ \int_0^{1.0} F_h \frac{dF_h}{d\eta} d\eta &= 3.7110 C_1^2 \\ \int_0^{1.0} F_\theta \frac{dF_\theta}{d\eta} d\eta &= 0.3183 C_2^2 \\ \int_0^{1.0} F_h \frac{d^2 F_h}{d\eta^2} d\eta &= 1.5926 C_1^2 \\ \int_0^{1.0} F_\theta \frac{d^2 F_\theta}{d\eta^2} d\eta &= -1.2337 C_2^2 \\ \int_0^{1.0} F_h F_\theta d\eta &= \int_0^{1.0} F_\theta F_h d\eta = -0.9233 C_1 C_2 \\ \int_0^{1.0} F_h \frac{dF_\theta}{d\eta} d\eta &= -1.4040 C_1 C_2 \\ \int_0^{1.0} F_\theta \frac{dF_h}{d\eta} d\eta &= -2.0669 C_1 C_2 \\ \int_0^{1.0} F_h \frac{d^2 F_\theta}{d\eta^2} d\eta &= 2.2782 C_1 C_2 \\ \int_0^{1.0} F_\theta \frac{d^2 F_h}{d\eta^2} d\eta &= -1.4722 C_1 C_2 \end{aligned}$$

The flutter determinant becomes

$$\begin{vmatrix} 1.8554C_1^2 \frac{V'}{b_r} A + 3.7110C_1^2 \left(i \frac{1}{k_n}\right) \left\{(-1) + A_{ea}\right\} \tan \Lambda - \left\{1.5926C_1^2 \frac{\tan^2 \Lambda}{V'/b_r} \frac{1}{k_n^2}\right\} & -0.9233C_1C_2 \frac{V'}{b_r} D - 2.0669C_1C_2 \left(i \frac{1}{k_n}\right) \left\{(a) + A_{ea}\right\} \tan \Lambda + \left\{-1.4722C_1C_2 \frac{\tan^2 \Lambda}{V'/b_r} \frac{a}{k_n^2}\right\} & -0.9233C_1C_2 \frac{V'}{b_r} B - (-1.4040C_1C_2) b_r A_{ea} \tan \Lambda + \left\{2.2782C_1C_2 b_r \frac{\tan^2 \Lambda}{V'/b_r} \frac{a}{k_n^2}\right\} \\ -0.9233C_1C_2 \frac{V'}{b_r} D - 2.0669C_1C_2 \left(i \frac{1}{k_n}\right) \left\{(a) + A_{ea}\right\} \tan \Lambda + \left\{-1.4722C_1C_2 \frac{\tan^2 \Lambda}{V'/b_r} \frac{a}{k_n^2}\right\} & A + 2.0000 \frac{\tan \Lambda}{V'/b_r} \left(i \frac{1}{k_n}\right) \left\{(-1) + A_{ea}\right\} - \left\{0.85837 \left(\frac{\tan \Lambda}{V'/b_r}\right)^2 \frac{1}{k_n^2}\right\} & 0.5000C_2^2 \frac{V'}{b_r} E - 0.3183C_2^2 b_r A_{ea} \tan \Lambda - \left\{-1.2337C_2^2 b_r \frac{\tan^2 \Lambda}{V'/b_r} \left(\frac{1}{8} + a^2\right) \frac{1}{k_n^2}\right\} \end{vmatrix} = 0$$

or more conveniently, when columns and rows of the determinant are divided by appropriate terms

$$\begin{vmatrix} A + 2.0000 \frac{\tan \Lambda}{V'/b_r} \left(i \frac{1}{k_n}\right) \left\{(-1) + A_{ea}\right\} - \left\{0.85837 \left(\frac{\tan \Lambda}{V'/b_r}\right)^2 \frac{1}{k_n^2}\right\} & B - 1.5206 \frac{\tan \Lambda}{V'/b_r} A_{ea} - \left\{2.4675 \left(\frac{\tan \Lambda}{V'/b_r}\right)^2 \frac{a}{k_n^2}\right\} \\ 0.9189D + 2.0571 \frac{\tan \Lambda}{V'/b_r} \left(i \frac{1}{k_n}\right) \left\{(a) + A_{ea}\right\} + \left\{1.4652 \left(\frac{\tan \Lambda}{V'/b_r}\right)^2 \frac{a}{k_n^2}\right\} & E - 0.63660 \frac{\tan \Lambda}{V'/b_r} A_{ea} + \left\{2.4675 \left(\frac{\tan \Lambda}{V'/b_r}\right)^2 \left(\frac{1}{8} + a^2\right) \frac{1}{k_n^2}\right\} \end{vmatrix} = 0$$

where

$$A = \frac{1}{K} \left[1 - \left(\frac{\omega_n}{\omega}\right)^2 (1 + i g_n) \right] - A_{ea}$$

$$B = \frac{x_{\alpha}}{K} - A_{ea}$$

$$D = \frac{x_{\alpha}}{K} - A_{ea}$$

$$E = \frac{r_{\alpha}^2}{K} \left[1 - \left(\frac{\omega_{\alpha}}{\omega}\right)^2 (1 + i g_{\alpha}) \right] - A_{ea}$$

It is interesting to note that the parameters Λ and V'/b_r appear only in the combination $\frac{\tan \Lambda}{V'/b_r}$ in the immediately preceding determinant. The solution of the determinant results in the flutter condition.

EXPERIMENTAL INVESTIGATION

APPARATUS

Wind tunnel.—The tests were conducted in the Langley 4.5-foot flutter research tunnel which is of the closed-throat, single-return type employing either air or Freon-12 as a testing medium at pressures varying from 4 inches of mercury to 30 inches of mercury. In Freon-12, the speed of sound is 324 miles per hour and the density is 0.0106 slug per cubic foot at standard pressure and temperature. The maximum choking Mach number for these tests was approximately 0.92. The Reynolds number range was from 0.26×10^6 to 2.6×10^6 with most of the tests at Reynolds numbers of the order of 1.0×10^6 .

Models.—In order to obtain structural parameters required for the flutter studies, different types of construction were used for the models. Some models were solid spruce, others were solid balsa, and many were combinations of balsa with various aluminum-alloy inserts. Seven series of models were investigated, for which the cross sections and plan forms are shown in figure 2.

Figure 2 (a) shows the series of models which were swept back by shearing the cross sections parallel to the air stream. In order to obtain flutter with these low-aspect-ratio models, thin sections and relatively light and weak wood construction were employed.

(a) Sheared swept models with a constant geometric aspect ratio of 2. Series I.

FIGURE 2.—Model plan form and cross-sectional construction.

(b) Models swept back by use of a rotating mount. Series II.

FIGURE 2.—Continued.

The series of rectangular-plan-form models shown in figure 2 (b) were swept back by using a base mount that could be rotated to give the desired sweep angle. The same base mount was used for testing models at forward sweep angles. It is known that for forward sweep angles divergence is critical. In an attempt to separate the divergence and flutter speeds in the sweepforward tests, a D-spar cross-sectional construction was used to get the elastic axis relatively far forward (fig. 2 (c)).

Two series of wings (figs. 2 (d) and 2 (e)) were swept back with the length-chord ratios kept constant. In these series of models, the chord perpendicular to the leading edge was kept constant and the bases were aligned parallel to the air stream. The wings of length-chord ratio 8.5 (fig. 2 (d)) were cut down to get the wings of length-chord ratio 6.5 (fig. 2 (e)).

Another series of models obtained by using this same manner of sweep (fig. 2 (f)) was used for investigating some effects of tip shape.

Spanwise strips of lead were fastened to the models shown in figure 2 (e) and a series of tests were conducted with these weighted models to determine the effect of center-of-gravity shift on the flutter speed of swept wings. The method of

(c) Models in which a rotating mount is used to determine the effect of sweepback and sweepforward on the critical velocity. Series III.

FIGURE 2.—Continued.

varying the center of gravity is shown in figure 2 (g). In order to obtain data at zero sweep angle it was necessary, because of the proximity of flutter speed to wing-divergence speed, to use three different wings. These zero-sweep-angle wings, of 8-inch chord and 48-inch length, had an internal weight system.

The models were mounted from the top of the tunnel as cantilever beams with rigid bases (fig. 3). Near the root of each model two sets of strain gages were fastened, one set for recording principally bending deformations and the other set for recording principally torsional deflections.

METHODS

Determination of model parameters.—Pertinent geometric and structural properties of the model are given in tables I to VII. Some parameters of interest are discussed in the following paragraphs.

As an indication of the nearness to sonic-flow conditions, the critical Mach number is listed. This Mach number is determined by the Kármán-Tsien method for a wing section normal to the leading edge at zero lift.

The geometric aspect ratio of a wing is here defined as

$$A_g = \frac{\text{Semispan}^2}{\text{Plan-form area}} = \frac{(l \cos \Lambda)^2}{lc} = \frac{l}{c} \cos^2 \Lambda = \frac{A}{2}$$

The geometric aspect ratio A_g is used in place of the conventional aspect ratio A because the models were only semispan wings. For sheared swept wings, obtained from a given unswept wing, the geometric aspect ratio is constant, whereas for the wings of constant length-chord ratio the geometric aspect ratio decreases with $\cos^2 \Lambda$ as the angle of sweep is increased.

The weight, center-of-gravity position, and polar moment of inertia of the models were determined by usual means. The models were statically loaded at the tip to obtain the rigidities in torsion and bending GJ and EI .

A parameter occurring in the methods of analysis of this report is the position of the elastic axis. A "section" elastic axis located at x_{ea} was obtained for wings from each series of models as follows: The wings were clamped at the root normal to the leading edge and at a chosen spanwise station

FIGURE 3.—Model 12 in the tunnel test section.

were loaded at points lying in the chordwise direction. The point for which pure bending deflection occurred, with no twist in the plane normal to the leading edge, was determined. The same procedure was used for those wings which were clamped at the root, not normal, but at an angle to the leading edge. A different elastic axis designated the "wing" elastic axis and located at x_{ea}' was thus determined.

For these uniform, swept wings with fairly large length-chord ratios, the wing elastic axis was reasonably straight and remained essentially parallel to the section elastic axis, although it was found to move farther behind the section elastic axis as the angle of sweep was increased. It is realized that in general for nonuniform wings—for example, wings with cut-outs or skewed clamping—a certain degree of cross stiffness exists and the concept of an elastic axis is an oversimplification. More general concepts such as those involving influence coefficients may be required. These more strict considerations, however, are not required here since the elastic-axis parameter is of fairly secondary importance.

The wing mass-density ratio κ is the ratio of the mass of a cylinder of testing medium, of a diameter equal to the chord of the wing, to the mass of the wing, both taken for unit length along the wing. The density of the testing medium when flutter occurred was used in the evaluation of κ .

Determination of the reference flutter speed.—It is convenient in presenting and comparing data of swept and unswept wings to employ a certain reference flutter speed. This reference flutter speed will serve to reduce variations in flutter characteristics which arise from changes in the various model parameters such as density and section properties not pertinent to the investigation. It thus aids in systematizing the data and emphasizing the desired effects of sweep including effects of aspect ratio and Mach number.

This reference flutter speed V_R may be obtained in the following way. Suppose the wing to be rotated about the intersection of the elastic axis with the root to a position of zero sweep. In this position the reference flutter speed is calculated by the method of reference 7, which assumes an idealized, uniform, infinite wing mounted on springs in an incompressible medium. For nonuniform wings, a reference section taken at a representative spanwise position, or some integrated value, may be used. Since the wings used were uniform, any reference section will serve. The reference flutter speed may thus be considered a "section" reference flutter speed and parameters of a section normal to the leading edge are used in its calculation. This calculation also employs the uncoupled first bending and torsion frequencies of the wing (obtained from the measured frequencies) and the measured density of the testing medium at time of flutter. The calculation yields a corresponding reference flutter frequency which is useful in comparing the frequency data. For the sake of completeness a further discussion of the reference flutter speed is given in appendix B.

Test procedure and records.—Since flutter is often a sudden and destructive phenomenon, coordinated test procedures were required. During each test, the tunnel speed was slowly raised until a speed was reached for which the

amplitudes of oscillation of the model in bending and torsion increased rapidly while the frequencies in bending and torsion, as observed on the screen of the recording oscillograph, merged to the same value. At this instant, the tunnel conditions were recorded and an oscillograph record of the model deflections was taken. The tunnel speed was immediately reduced in an effort to prevent destruction of the model.

From the tunnel data, the experimental flutter speed V_e , the density of the testing medium ρ , and the Mach number M were determined. No blocking or wake corrections to the measured tunnel velocity were applied.

From the oscillogram the experimental flutter frequency f_e and the phase difference φ (or the phase difference $\pm 180^\circ$) between the bending and torsion deflections near the root were read. A reproduction of a typical oscillograph flutter record, which indicated the flutter to be a coupling of the wing bending and torsion degrees of freedom, is shown as figure 4. Since semispan wings mounted rigidly at the base were used, the flutter mode may be considered to correspond to the flutter of a complete wing having a very heavy fuselage at midspan—that is, to the symmetrical type.

The natural frequencies of the models in bending and torsion at zero airspeed were recorded before and after each test in order to ascertain possible changes in structural characteristics. In most cases there were no appreciable changes in frequencies but there were some reductions in stiffnesses for models which had been weakened by fluttering violently. Analysis of the decay records of the natural frequencies indicated that the wing damping coefficients g_b and g_a (reference 7) were about 0.02 in the first bending mode and 0.03 in the torsion mode.

RESULTS AND DISCUSSION

EXPERIMENTAL INVESTIGATION

Presentation of experimental data.—Results of the experimental investigation are listed in detail in tables I to VII, and some significant experimental trends are illustrated

FIGURE 4.—Oscillograph record of model at flutter.

in figures 5 to 10. As a basis for presenting and comparing the test results, the ratio of experimental tunnel stream conditions to the reference flutter conditions is employed so that the data indicate more clearly combined effects of aspect ratio, sweep, and Mach number. As previously mentioned, use of the reference flutter speed V_R serves to reduce variations in flutter characteristics which arise from changes in other parameters, such as density and section properties, which are not pertinent to this investigation. (See appendix B.)

Some effects on flutter speed.—A typical plot showing the effect of compressibility on the flutter speed of wings at various angles of sweepback is shown in figure 5. These data are from tests of the rectangular-plan-form models (type 30) that were swept back by use of the rotating mount, for which arrangement the reference flutter speed does not vary with either Mach number or sweep angle. Observe the large increase in speed ratio at the high sweep angles.

The data of reference 1 from tests of a rigid, flexibly mounted rectangular model having a rotating base are also plotted in figure 5. It can be seen that the data from the cantilever models of the present report which had a similar method of sweep are in conformity with the data from the flexibly mounted model. This indicates that, for uniform wings having the range of parameters involved in these tests, the differences due to mode shape are not very great.

Figure 6 is a cross plot of the data from figure 5 plotted against Λ at a Mach number approximately equal to 0.65. The data of the swept wings of constant length-chord ratio and of the sheared swept wings are also included for comparison. The velocity ratio V_e/V_R is relatively constant at small sweep angles but rises noticeably at the large sweep angles. It is pointed out that the reference flutter speed V_R may be considered to correspond to a horizontal line at $\frac{V_e}{V_R}=1$ for the rotated and constant-length-chord-ratio wings, but for the sheared wings this reference speed corresponds to a curve decreasing somewhat less rapidly than $\sqrt{\cos \Lambda}$ as Λ increases. (See appendix B.)

FIGURE 5.—Ratio of experimental to reference flutter speed as a function of Mach number for various sweep angles for series II models (fig. 2 (b)) on the rotating mount.

The order of magnitude of some three-dimensional effects may be noted from the fact that the shorter wings ($\frac{l}{c}=6.5$, fig. 6, series V) have higher velocity ratios than the longer wings ($\frac{l}{c}=8.5$, series IV). This increase may be due partly to differences in flutter modes as well as aerodynamic effects.

Some effects on flutter frequency.—Figure 7 is a representative plot of the flutter-frequency data given in table II. The figure shows the variation in flutter-frequency ratio with Mach number for different values of sweep angle for the models rotated back on the special mount. The ordinate

FIGURE 6.—Cross plot of ratio of experimental to reference flutter speed as a function of sweep angle for various wings. Mach number is approximately 0.65.

FIGURE 7.—Ratio of experimental to reference flutter frequency as a function of Mach number for various sweep angles for series II models (fig. 2 (b)) on the rotating mount.

is the ratio of the experimental flutter frequency to the reference flutter frequency f_e/f_R . It appears that there is a reduction in flutter frequency with increase in Mach number and also an increase in flutter frequency with increase in sweep. The data from reference 1 show the same trend with increase in sweep. Considerably more scatter may be noted in the frequency data than in the speed data (fig. 5) from the same tests.

The results of the tests for rotated wings with chordwise laminations (models 40A, B, C, D) are given in table II. At sweep angles up to 30° the values of the speed ratio V_e/V_R for wings of this construction were low (in the neighborhood of 0.9), and the flutter frequency ratios f_e/f_R were high (of the order of 1.4). As these results indicate and as visual observation showed, these models fluttered in a mode that apparently involved an appreciable proportion of the second bending mode. The models with spanwise laminations (models 30A, B, C, D) also showed indications of this higher flutter mode at low sweep angles; however, these models were able to pass through the small speed range of higher mode flutter without sufficiently violent oscillations to cause failure. At a still higher speed these models with spanwise laminations fluttered in a lower mode resembling a coupling of the torsion and first bending modes. This lower mode type of flutter characterized the flutter of both the sheared and constant-length-chord-ratio models.

For those wing models having the sheared type of balsa construction (models 22', 23, 24, and 25), the results are more difficult to compare with those of the other models. This difficulty arises chiefly because the lightness of the wood produced relatively high mass-density ratios κ and partly because of the nonhomogeneity of the mixed wood construction. For high values of κ the flutter-speed coefficient changes rather abruptly even for the unswept models (reference 7). The data are nevertheless included in table I.

Effect of shift in center-of-gravity position on the flutter speed of swept wings.—Results of the investigation of the effects of center-of-gravity shift on the flutter speed of swept wings are illustrated in figure 8. This figure is a cross plot of the experimental indicated air speeds as a function of sweep angle for various center-of-gravity positions. The ordinate is the experimental indicated air

speed $V_e \sqrt{\frac{\rho}{0.00238}}$, which serves to reduce the scatter resulting from flutter tests at different densities of testing medium. The data were taken in the Mach number range between 0.14 and 0.44, so that compressibility effects are presumably negligible. As in the case of unswept wings, forward movement of the center of gravity increases the flutter speed. Again, the flutter speed increases with increase in the angle of sweep.

The models tested at zero sweep angle (models 91-1, 91-2, 91-3) were of different construction from and of larger size than the models tested at the higher sweep angles. Because of the manner of plotting the results, namely as experimental indicated airspeed (fig. 8), a comparison of the results of tests at $\Lambda=0^\circ$ with the results of the tests of swept models

is not particularly significant. The points at zero sweep angle are included, however, to show that the increase in flutter speed due to a shift in the center-of-gravity position for the swept models is of the same order of magnitude as for the unswept models. For the unswept models, the divergence speed V_D and the reference flutter speed V_R are fairly near each other, and although the models appeared to flutter, the proximity of the flutter speed to the divergence speed may have influenced the value of the critical speed.

The method used to vary the center of gravity (see fig. 2 (g)) produced two bumps on the airfoil surface. At the low Mach numbers of these tests, however, the effect of this roughness on the flutter speed is considered negligible. For proper interpretation of figure 8, the fact must be kept in mind that the method of varying the location of the center of gravity changed the radius of gyration r_a and the torsional frequency f_a .

The effect of sweepforward on the critical speed.—An attempt was made to determine the variation in flutter speed with angle of sweepforward by testing wings on the mount that could be rotated both backward and forward. As expected, however, the model tended to diverge at forward sweep angles in spite of the relatively forward position of the elastic axis in this D-spar wing.

Figure 9 shows a plot of the ratio of critical speed to the reference flutter speed V_R against sweep angle Λ . Note the different curves for the sweptback and for the sweptforward conditions and the sharp reduction in critical speed as the

FIGURE 8.—Cross plot of flutter speed as a function of sweep angle for several center-of-gravity positions. Series VII models (fig. 2 (g)). Length-chord ratio is approximately 6.

FIGURE 9.—Comparison of sweepforward and sweepback tests on wings tested on a rotating mount. Series III models (fig. 2 (c)).

angle of sweepforward is increased. The different curves result from two different phenomena. When the wing was swept back, it fluttered; whereas at forward sweep angles it diverged before the flutter speed was reached. Superposed on this plot for the negative values of sweep are the results of calculations based on an analytical study of divergence (reference 9). Reasonable agreement exists between theory and experiment at forward sweep angles. The small difference between the theoretical and experimental results may perhaps be due to an inaccuracy in determining either the position of the elastic axis of the model or the required slope of the lift curve or both.

The divergence speed V_D for the wing at zero sweep angle, as calculated by the simplified theory of reference 7, is also plotted in figure 9. This calculation is based on the assumption of a two-dimensional unswept wing in an incompressible medium. The values of the uncoupled torsion frequency and the density of the testing medium at time of flutter or divergence are employed. Reference 9 shows that a relatively small amount of sweepback raises the divergence speed sharply. For convenience, however, the numerical quantity V_D (based on the wing at zero sweep) is listed in table I for all the tests.

Effect of tip modifications.—Tests to investigate some of the over-all effects of tip shape were conducted and some results are shown in figure 10. Two sweep angles and two length-chord ratios were used in the experiments conducted at two Mach numbers. It is seen that, of the three tip shapes used, namely, tips perpendicular to the air stream, perpendicular to the wing leading edge, and parallel to the air stream, the wings with tips parallel to the air stream gave the highest flutter speeds.

DISCUSSION AND COMPARISON OF ANALYTICAL AND EXPERIMENTAL RESULTS

Correlation of analytical and experimental results has been made for wings swept back in the two different manners; that is, (1) sheared back with a constant value of A_g , and (2) rotated back. The two types of sheared wings (series I) and two rotated wings (models 30B and 30D) have been analyzed.

FIGURE 10.—Effect of tip shape on the flutter speed of swept wings. Wings of length-chord ratios of 7.25 and 11 (fig. 2 (f)). Series VI models.

Results of some solutions of the flutter determinant for a wing (model 30B) on a rotating base at several angles of sweepback are shown in figures 11 and 12. Figure 11 shows the flutter-speed coefficient as a function of the bending-to-torsion frequency ratio, and figure 12 shows the flutter frequency ratio as a function of the bending-to-torsion frequency ratio.

The calculated results (for those wings investigated analytically) are included in tables I and II. The ratios of experimental to analytical flutter speeds and flutter frequencies have been plotted against the angle of sweep in figures 13 to 16. If an experimental value coincides with the corresponding analytical predicted value, the ratio will fall at a value of 1.0 on the figures. Deviations of experimental results above or below the analytical results appear on the figures as ratios greater than or less than 1.0, respectively. The flutter-speed ratios plotted in figure 13 for the two rotated wings show very good agreement between analysis and experiment over the range of sweep angle, 0° to 60° . Such good agreement in both the trends and in the numerical quantities is gratifying but probably should not be expected in general. In view of the discussion of the last term in equation (5b) it may be of interest to mention that failure to include the terms arising from the last term of equation (5b) in the calculations for model 30B would decrease the ratio V_e/V_a corresponding to $\Lambda = 60^\circ$ by about 3 percent. The flutter frequency ratios of figure 14 obtained from the same two rotated wings are in good agreement.

The flutter-speed ratios plotted in figure 15 for the two types of sheared wings do not show such good conformity at the low angles of sweep, whereas for sweep angles beyond 45° the ratios are considerably nearer to 1.0. The sheared wings are again observed to have a constant value of A_g of 2.0 (aspect ratio for the whole wing would be 4.0). For this small value of aspect ratio the finite-span correction is appreciable at zero angle of sweep and, if made, would bring better agreement at that point. Analysis of the corrections for finite-span effects on swept wings requires further consideration.

Figures 13 and 15 also afford a comparison of the behavior of wings swept back in two manners: (1) rotated back with

FIGURE 11.—Theoretical flutter-speed coefficient as a function of the ratio of bending to torsion frequency for the rotated model 30B at four angles of sweep and with a constant mass-density ratio ($\frac{1}{\kappa}=37.8$).

constant length-chord ratio but decreasing aspect ratio (fig. 13), and (2) sheared back with constant aspect ratio and increasing length-chord ratio (fig. 15). A study of these two figures suggests that the length-chord ratio rather than the aspect ratio ($\frac{\text{Span}^2}{\text{Area}}$) may be the relevant parameter in determining corrections for finite swept wings. (Admittedly, effects of tip shape and root condition are also involved and have not been precisely separated.)

Figure 16, which refers to the same sheared wings as figure 15, shows the ratios of experimental to predicted flutter frequencies. The trend is for the ratio to decrease as the angle of sweep increases. Table I shows that the flutter frequency f_R obtained with V_R and used as a reference in a previous section of the report is not significantly different from the frequency f_Λ predicted by the present analysis.

A few remarks can be made on estimates of over-all trends of the flutter speed of swept wings. As a first consideration the conclusion may be made that, if a rigid infinite yawed

FIGURE 12.—Ratio of theoretical flutter frequency to torsional frequency as a function of the ratio of bending to torsion frequency for the rotated model 30B at two angles of sweep and with a constant mass-density ratio ($\frac{1}{\kappa}=37.8$).

FIGURE 13.—Ratio of experimental to theoretically predicted flutter speed as a function of sweep angle for two rotated models.

wing were mounted on springs which permitted it to move vertically as a unit and to rotate about an elastic axis, the flutter speed would be proportional to $1/\cos \Lambda$. A finite yawed wing mounted on similar springs would be expected to have a flutter speed lying above the curve of $1/\cos \Lambda$ because of finite-span effects. For a finite sweptback wing clamped at its root, however, the greater degree of coupling between bending and torsion adversely affects the flutter speed so as to bring the speed below the curve of $1/\cos \Lambda$ for an infinite wing. This statement is illustrated in figure 17 which refers to a wing (model 30B) on a rotating base. The ordinate is the ratio of flutter speed at a given angle of sweep to the flutter speed calculated at zero angle of sweep. A theoretical curve is shown, together with experimentally determined points. Curves of $1/\cos \Lambda$ and $1/\sqrt{\cos \Lambda}$ are shown for convenience of comparison. The curve for model 30D (not shown in figure 17) also followed this trend quite closely. The foregoing remarks should prove useful for making estimates and discussing trends but are not intended to replace more complete calculation. In particular, mention may be made, for example, that a far-forward location

FIGURE 14.—Ratio of experimental to theoretically predicted flutter frequency as a function of sweep angle for two rotated models.

FIGURE 15.—Ratio of experimental to theoretically predicted flutter speed as a function of sweep angle for two types of sheared models.

of section center of gravity would lead to an entirely different trend. Moreover, as is apparent from the analysis, the bending stiffness can play an increasingly significant role with increase in the angle of sweep.

The experiments and calculations deal in general with wings having low ratios of natural first bending to first torsion frequencies. At high values of the ratio of bending frequency to torsion frequency, the position of the elastic axis becomes relatively more significant. Additional calculations to develop the theoretical trends are desirable.

CONCLUSIONS

In a discussion and comparison of the results of an investigation of the flutter of a group of swept wings, the manner of sweep is significant. This report deals with two main groups of uniform, swept wings: rotated wings and sheared wings. In presenting the data, employment of a certain reference flutter speed was found convenient. The following conclusions seem to apply:

1. Comparison with experiment indicates that the analysis presented is satisfactory for giving the main effects of sweep, at least for nearly uniform cantilever wings of moderate length-chord ratios. Additional calculations are desirable to investigate various theoretical trends.

2. The coupling between bending and torsion adversely affects the flutter speed. The fact, however, that only a part of the forward velocity is aerodynamically effective

FIGURE 16.—Ratio of experimental to theoretically predicted flutter frequency as a function of sweep angle for two types of sheared wings.

FIGURE 17.—Flutter-speed ratio as a function of sweep angle for model 30B at a constant mass-density ratio ($\frac{1}{\kappa}=37.8$), showing analytical and experimental results.

increases the flutter speed. Certain approximate relations can be used to estimate some of the trends.

3. Although a precise separation of the effects of Mach number, aspect ratio, tip shape, and center-of-gravity position has not been accomplished, the order of magnitude of some of these combined effects has been experimentally determined. Experimental results indicated are

(a) The location of the section center of gravity is an important parameter and produces effects for swept wings similar to those for unswept wings over the range (30 percent to 70 percent chord) of locations tested.

(b) Appreciable differences in flutter speed have been found to be due to tip shape.

(c) The length-chord ratio of swept wings is a more relevant finite-span parameter than is the aspect ratio.

(d) Compressibility effects attributable to Mach number are fairly small, at least up to a Mach number of 0.8.

(e) The sweptforward wings could not be made to flutter but diverged before the flutter speed was reached.

LANGLEY FIELD, VA., September 9, 1948.

APPENDIX A

THE EFFECT OF SWEEP ON THE FREQUENCIES OF A CANTILEVER BEAM

Early in the investigation it was decided to make an experimental vibration study of a simple beam at various sweep angles. The uniform, plate-like aluminum-alloy beam shown in figure 18 was used to make the study amenable to analysis. Length-chord ratios of 6, 3, and 1.5 were tested, the length l being defined as the length along the midchord. A single 60-inch beam was used throughout the investigation, the desired length and sweep angle being obtained by clamping the beam in the proper position with a 1½- by 1½- by 14-inch aluminum-alloy crossbar.

Figures 18 and 19 show the variation in modes and frequencies with sweep angle. In most cases, an increase in sweep angle increased the natural vibrational frequencies. As expected, the effect of sweep was more pronounced at the

FIGURE 18.—Change in nodal lines with sweep and length-chord ratio for the vibration of an aluminum-alloy beam.

smaller values of length-chord ratio. The fundamental mode was found by striking the beam and measuring the frequency with a self-generating vibration pick-up and paper recorder. The second and third modes were excited by light-weight electromagnetic shakers clamped to the beam. These shakers were attached as close to the root as possible to give a node either predominantly spanwise or chordwise. The mode with the spanwise node, designated second mode, was primarily torsional vibration, whereas the mode with the chordwise node, designated third mode, was primarily a second bending vibration.

The first two bending frequencies and the lowest torsion frequency, determined analytically for a straight uniform unswept beam, are plotted in figure 19. Good agreement exists with the experimental results for the length-chord ratios of 6 and 3, but for a ratio of 1.5 (length equal to 12 inches and chord equal to 8 inches) less favorable agreement exists. This discrepancy may be attributed to the fact that the beam at the short length-chord ratio of 1.5 resembled more a plate than a beam and did not meet the theoretical assumptions of a perfectly rigid base and of simple-beam stress distributions. The data are valid for use in comparing the experimental frequencies of the beam when swept with the frequencies at zero sweep, which was the purpose of the test.

FIGURE 19.—Variation of frequencies with sweep and length-chord ratio for the vibration of an aluminum-alloy beam.

APPENDIX B

DISCUSSION OF THE REFERENCE FLUTTER SPEED

For use in comparing data of swept and unswept wings, a reference flutter speed V_R is convenient. This reference flutter speed is the flutter speed determined from the simplified theory of reference 7. This theory deals with two-dimensional unswept wings in incompressible flow and depends upon a number of wing parameters. The calculations in this report utilize parameters of sections perpendicular to the leading edge, first bending frequency, uncoupled torsion frequency, density of testing medium at time of flutter, and zero damping. Symbolically,

$$V_R = b \omega_\alpha f \left(\kappa, x_{cg}, x_{ea}, r_\alpha^2, \frac{f_h}{f_\alpha} \right)$$

Variation in reference flutter speed with sweep angle for sheared swept wings.—The reference flutter speed is independent of sweep angle for a homogeneous rotated wing and for homogeneous wings swept back by keeping the length-chord ratio constant. For a series of homogeneous wings swept back by the method of shearing, however, a definite variation in reference flutter speed with sweep angle exists since sweeping a wing by shearing causes a reduction in chord perpendicular to the wing leading edge and an increase in length along the midchord as the angle of sweep is increased. The resulting reduction in the mass-density-ratio parameter and first bending frequency tends to raise the reference flutter speed, whereas the reduction in semichord tends to lower the reference flutter speed as the angle of sweep is increased. The final effect upon the reference flutter speed depends on the other properties of the wing. The purpose of this section is to show the effect of these changes on the magnitude of the reference flutter speed for a series of homogeneous sheared wings having properties similar to those of the sheared swept models used in this report.

Let the subscript 0 refer to properties of the wing at zero sweep angle. The following parameters are then functions of the sweep angle:

$$b = b_0 \cos \Lambda$$

$$l = \frac{l_0}{\cos \Lambda}$$

Since m is proportional to b ,

$$\kappa = \frac{\pi \rho b^2}{m} = \kappa_0 \cos \Lambda$$

Similarly, since I is proportional to b ,

$$f_{h1} = \frac{0.56}{l^2} \sqrt{\frac{EI}{m}} = (f_{h1})_0 (\cos \Lambda)^2$$

Also, because f_α is independent of Λ ,

$$\frac{f_{h1}}{f_\alpha} = \left(\frac{f_{h1}}{f_\alpha} \right)_0 (\cos \Lambda)^2$$

An estimate of the effect on the flutter speed of these changes in semichord and mass parameter with sweep angle may be obtained from the approximate formula given in reference 7,

$$V_R \approx b \omega_\alpha \sqrt{\frac{r_\alpha^2}{\kappa} \frac{0.5}{0.5 + a + x_\alpha}} = V_{R_0} \sqrt{\cos \Lambda}$$

This approximate analysis of the effect on the reference flutter speed does not depend upon the first bending frequency but assumes f_h/f_α to be small.

In order to include the effect of changes in bending-torsion frequency ratio, a more complete analysis must be carried out. Figure 20 presents some results of a numerical analysis based on a homogeneous wing with properties at zero sweep angle as follows:

$$\begin{array}{ll} x_{cg} = 50 & b_0 = 0.333 \\ x_{ea} = 45 & \left(\frac{1}{\kappa} \right)_0 = 10 \\ r_\alpha^2 = 0.25 & \\ f_\alpha = 100 & \left(\frac{f_{h1}}{f_\alpha} \right)_0 = 0.4 \end{array}$$

In figure 20 the curve showing the decrease in V_R with Λ is slightly above the $\sqrt{\cos \Lambda}$ factor indicated by the approximate formula.

Effect of elastic-axis position on reference flutter speed.—As pointed out in the definition of elastic axis, the measured

FIGURE 20.—Variation in reference flutter speed with sweep for sheared wings.

locus of elastic centers x_{ea}' fell behind the section elastic axis for the swept models with bases parallel to the air stream. In order to get an idea of the effect of elastic-axis position on the chosen reference flutter speed, computations were made both of V_R and a second reference flutter speed V_R' similar to V_R except that x_{ea}' was used in place of x_{ea} . The maximum difference between these two values of reference flutter speed was of the order of 7 percent. This difference occurred at a sweep angle of 60° when the wing elastic axis was farthest behind the section elastic axis. Thus, for wings of this type,

the reference flutter speed is not very sensitive to elastic-axis position. The reference flutter frequency f_R' was found in conjunction with V_R' . The maximum difference between f_R and f_R' was less than 10 percent. Thus, the convenient use of the reference flutter speed and reference frequency is not altered by these elastic-axis considerations.

REPORT 1015

ANALYSIS OF TURBULENT FREE-CONVECTION BOUNDARY LAYER ON FLAT PLATE¹

By E. R. G. ECKERT AND THOMAS W. JACKSON

SUMMARY

With the use of Kármán's integrated momentum equation for the boundary layer and data on the wall-shearing stress and heat transfer in forced-convection flow, a calculation was carried out for the flow and heat transfer in the turbulent free-convection boundary layer on a vertical flat plate. The calculation is for a fluid with a Prandtl number that is close to 1.

A formula was derived for the heat-transfer coefficient that was in good agreement with experimental data in the range of Grashof numbers from 10^{10} to 10^{12} . Because of the good agreement between the theoretical formula and the experimental data, the formula may be used to obtain data for higher Grashof numbers. The calculation also yielded formulas for the maximum velocity in the boundary layer and for the boundary-layer thickness.

INTRODUCTION

Recent developments in the field of gas turbines have revealed the need for data on heat transfer in turbulent free-convection flow at very high Grashof numbers (10^{12} to 10^{15}). For example, in using the method of free-convection cooling for turbine blades, the centrifugal forces generate a free-convection flow of the cooling fluid in the blade passages that is within the preceding range of Grashof numbers. Free-convection flow is also superimposed on the flow of the cooling air in the hollow blades of air-cooled gas turbines and may influence considerably the heat transfer under certain conditions. The radial flow present in the cooled boundary layers on the outside of cooled turbine blades is also of a type similar to the free-convection flow in the blade coolant passages.

In order to understand and to evaluate such cooling processes, information on the heat transfer, the boundary-layer thickness, and the velocities connected with free-convection flow is necessary. The knowledge of turbulent free-convection flow, however, is limited. Experiments on plane vertical surfaces give heat-transfer data up to Grashof times Prandtl numbers of 10^{12} (summarized in references 1 and 2). Griffiths and Davis (reference 3) determined, in addition, temperature and velocity profiles. Watzinger and Johnson (reference 4) measured heat transfer and temperature and velocity profiles in a superimposed forced- and free-convection flow in a vertical tube. Brown and Marko (reference 5) show by theoretical considerations that a gen-

eral relation exists between the Grashof number that characterizes free-convection flow and the Reynolds number that characterizes forced flow. Colburn and Hougen (reference 6) derive a formula for the heat transfer in turbulent free-convection flow on a vertical plate. However, only the laminar sublayer in the immediate neighborhood of the wall was investigated in reference 6 and the thickness of this sublayer, made dimensionless by the shearing stress velocity and the kinematic viscosity, was assumed to be the same as in forced flow. This analysis therefore gives no information on the whole boundary-layer thickness and on the velocities.

The problem of turbulent free-convection flow is approached herein using another method. Certain shapes are assumed for the temperature and velocity profiles in the free-convection boundary layer. In addition, an empirical relation for the shearing stress on the wall and a heat-transfer coefficient derived from forced-convection flow are used to estimate the boundary-layer thickness, the maximum velocity within the boundary layer, and a heat-transfer coefficient for free-convection flow. No experimental free-convection measurements are used in the calculations.

SHEARING STRESS AND HEAT FLOW IN FORCED-CONVECTION BOUNDARY LAYER

The relations for forced-convection flow that are needed in the theoretical free-convection calculations are compiled in this section. It is known that for Reynolds numbers that are not too high, the velocity profile in a turbulent boundary layer on a flat plate can be represented by the equation

$$u = u_1 \left(\frac{y}{\delta} \right)^{1/7} \quad (1)$$

(All symbols are defined in the appendix.) The shearing stress on the plate surface in such a flow is given by the equation (reference 7,)

$$\tau_w = 0.0225 \rho u^2 \left(\frac{\nu}{uy} \right)^{1/4} \quad (2)$$

This equation is the relation for the shearing stress on the wall that is used in the derivation of the boundary-layer equations for the turbulent free-convection boundary layer. By introducing equation (1), the velocity profile, the shear-

¹ Supersedes NACA TN 2207, "Analysis of Turbulent Free-Convection Boundary Layer on Flat Plate" by E. R. G. Eckert and Thomas W. Jackson, 1950.

ing stress can also be expressed by the velocity u_1 at the outer edge of the boundary layer and by the boundary-layer thickness δ :

$$\tau_w = 0.0225 \rho u_1^2 \left(\frac{\nu}{u_1 \delta} \right)^{1/4} \quad (3)$$

For fluids or gases with a Prandtl number equal to 1, the temperature profile is similar in shape to the velocity profile. When the temperatures within the boundary layer are measured with the temperature outside the boundary layer as reference, the expression for the temperature profile is

$$\theta = \theta_w \left[1 - \left(\frac{y}{\delta} \right)^{1/7} \right] \quad (4)$$

Equation (4) is valid for values of y less than δ . For larger values of y , $\theta = 0$.

Reynolds analogy between the turbulent exchange of momentum and heat gives the relation (reference 8)

$$\frac{q_w}{\tau_w} = g c_p \frac{dt}{du} \quad (5)$$

Because the temperature and velocity profiles are similar in shape for a Prandtl number equal to 1, the finite temperature and velocity differences at two arbitrary points in the flow can be introduced into the last equation instead of the differentials. Using the differences between the wall and the flow outside the boundary layer and specifying the heat flow and the shearing stress for the position at the wall give the following equation:

$$\frac{q_w}{\tau_w} = g c_p \frac{\theta_w}{u_1} \quad (6)$$

The introduction of the law (equation (3)) for the shearing stress into this expression yields the following equation:

$$q_w = 0.0225 g \rho c_p u_1 \theta_w \left(\frac{\nu}{u_1 \delta} \right)^{1/4} \quad (7)$$

Heat transfer is usually calculated with dimensionless moduli. Such a modulus is the Stanton number

$$St = \frac{q_w}{g \rho c_p u_1 \theta_w} = 0.0225 \left(\frac{\nu}{u_1 \delta} \right)^{1/4}$$

Experimental investigations show that for fluids with Prandtl numbers from approximately 0.5 to 50 (reference 1, p. 520) the same relation holds when it is multiplied by the factor $Pr^{-2/3}$.

$$St = \frac{q_w}{g \rho c_p u_1 \theta_w} = 0.0225 \left(\frac{\nu}{u_1 \delta} \right)^{1/4} (Pr)^{-2/3} \quad (8)$$

This relation for the heat flow q_w is used in the derivation of the boundary-layer equations for the turbulent free-convection boundary layer.

Replacing the boundary-layer thickness δ by

$$\delta = 0.366 x \left(\frac{\nu}{u_1 x} \right)^{1/5}$$

which is the boundary-layer thickness on a flat plate in turbulent forced-convection flow (reference 1, p. 481), transforms equation (8) into the widely accepted formula for heat transfer on a flat plate in the turbulent range

$$Nu = \frac{q_w x}{k \theta_w} = 0.029 \left(\frac{u_1 x}{\nu} \right)^{0.8} (Pr)^{1/3} \quad (9)$$

DETERMINATION OF TURBULENT FREE-CONVECTION BOUNDARY LAYER

DERIVATION OF BOUNDARY-LAYER EQUATIONS

If a stationary plane vertical wall is heated to a temperature higher than the surroundings, the layer of fluid adjacent to the wall is heated by conduction from the wall. In this way, buoyant forces are generated that cause this layer to flow in an upward direction. This layer of fluid adjacent to the wall to which the vertical motion is confined is called the free-convection boundary layer. The boundary layer begins with zero thickness at the lower end of the vertical wall and increases in thickness in the upward direction. At a certain distance from the lower end of the wall the boundary layer becomes turbulent, depending on the critical Grashof number. The distance measured vertically from the lower end of the wall is called x and the distance normal to the wall y . In order to determine the boundary-layer thickness for steady state, a small stationary volume element in the turbulent region of the boundary layer is considered. Figure 1 shows this volume element. The dimensions of the element are dx along the wall and l normal to the wall. The length l should be larger than the boundary-layer thickness δ . For two-dimensional flow, the dimension of the volume element normal to the plane of figure 1 may be considered to be 1. The upward velocity of the fluid in plane 1-1 at a distance y from the surface of the wall is u . Then the mass flow through a small area with a width dy is $\rho u dy$ and the flow of momentum in the x -direction is $\rho u^2 dy$. The momentum flow in the x -direction entering the volume element through plane 1-1 is

$$\int_0^l \rho u^2 dy$$

In progressing to plane 2-2 the momentum flow changes by

$$\frac{d}{dx} \left(\int_0^l \rho u^2 dy \right) dx$$

The mass flow entering the volume element through plane 1-1 is generally different from the mass flow leaving the element through plane 2-2. Therefore fluid enters or leaves the volume element through the plane parallel to the wall at a distance l . Because it is assumed that the velocity in the x -direction outside the boundary layer is so small that it can be neglected, no momentum in the x -direction is carried through the plane.

The rate of change of momentum must be in equilibrium with the forces acting in the x -direction on the fluid within or on the surface of the volume element considered. A shearing stress τ_w acts on the wall. The force connected with

this stress is $\tau_w dx$. No shearing stress occurs on the surface of the volume element that is parallel to the wall and at a distance l from the wall because outside the boundary layer the velocity in the x -direction is zero.

According to the boundary-layer theory, the pressure change can be neglected along any normal to the surface. A constant pressure difference dp therefore exists between planes 1-1 and 2-2. This pressure difference gives a force on the volume element of magnitude $l dp$. In addition to the forces on the surfaces, there is a force due to the weight of the fluid within the volume element

$$\left(\int_0^l \rho g dy \right) dx$$

The process of summing up all the forces and equating them to the change in momentum flow gives the momentum equation

$$\frac{d}{dx} \left(\int_0^l \rho u^2 dy \right) dx = l dp - \left(\int_0^l \rho g dy \right) dx - \tau_w dx$$

Because no flow exists outside the boundary layer, the pressure difference between planes 1-1 and 2-2 is balanced by the weight of the fluid layer between the planes

$$dp = \rho_s g dx$$

When both sides of this equation are multiplied by l and the right side of the equation is changed to the integral form, the following equation is obtained

$$l dp = \left(\int_0^l \rho_s g dy \right) dx$$

Introducing the preceding equation into the momentum equation gives

$$\frac{d}{dx} \left(\int_0^l \rho u^2 dy \right) dx = g \left[\int_0^l (\rho_s - \rho) dy \right] dx - \tau_w dx$$

Introducing the expansion coefficient defined by the equation

$$\beta = \frac{v - v_s}{v_s} \left(\frac{1}{t - t_s} \right)$$

the first term on the right side of the preceding equation can be transformed into

$$g dx \int_0^l \beta \rho (t - t_s) dy$$

Designating the difference between the temperature t at the distance y and the temperature t_s outside the boundary layer by θ , the following expression is obtained:

$$g dx \int_0^l \beta \rho \theta dy$$

In the applications considered, the essential influence of the density changes on the flow is taken into account by the introduction of the expansion coefficient β . The other influences of variable density on the flow and the variation of

the expansion coefficient β with small temperature differences are negligible. Therefore, β and ρ can be assumed constant in the preceding expressions. The momentum equation for the free-convection boundary layer therefore becomes

$$\frac{d}{dx} \int_0^l u^2 dy = g \beta \int_0^l \theta dy - \frac{\tau_w}{\rho} \quad (10)$$

A similar equation is set up for the heat flow through the volume element in figure 1. The heat carried with the fluid through plane 1-1 is

$$g \rho c_p \int_0^l u \theta dy$$

where the enthalpies $c_p \theta$ are measured from the temperature outside the boundary layer. The specific heat and density are considered constant.

FIGURE 1.—Nomenclature in deriving equations for free-convection boundary layer.

The heat carried out of plane 2-2 differs from that carried into plane 1-1 by

$$g \rho c_p \frac{d}{dx} \left(\int_0^l u \theta dy \right) dx$$

The difference in the heat flow through planes 1-1 and 2-2 must come from the surface and the heat flow leaving the plate per unit time and area is therefore

$$q_w = g \rho c_p \frac{d}{dx} \int_0^l u \theta dy \quad (11)$$

Equation (11) is the heat-flow equation for the free-convection boundary layer.

Equations for the laminar free-convection boundary layer that are analogous to equations (10) and (11) were derived and solved by Squire. (See reference 9.)

SOLUTION OF BOUNDARY-LAYER EQUATIONS

Equations (10) and (11) are sufficient to calculate the boundary-layer thickness δ and the velocity u when the shape of the velocity and temperature profiles within the boundary layer and the laws for the shearing stress and the

heat flow on the wall are known. It was suggested by von Kármán that an approximate solution may be obtained by introducing approximate shapes for both profiles (reference 7). The accuracy of the solution is better the more closely the assumed shapes correspond to the real profiles. The method, however, proved comparatively insensitive to changes in the profile shape.

As mentioned in the section "INTRODUCTION" some information on the shape of the velocity and temperature profiles in turbulent free-convection flow can be obtained from reference 3. In figure 2, the measured values of both profiles in the turbulent range are presented with the ratios θ/θ_w and u/u_{max} plotted against the distance from the wall in an arbitrary scale. The value u_{max} was determined by drawing curves through the measured velocity values given in table VI of reference 3.

The distance from the wall where the curves u/u_{max} have the value 0.5 was arbitrarily assigned the value 1. The lines in figure 2 are the curves by which the temperature and velocity profiles are approximated herein. These profiles are presented in figure 2 in such a way that the velocity profile has the value 0.5 at a distance 1 and the temperature profile the value 0.2 at a distance 0.5 from the wall. An indication of the shape of turbulent free-convection flow profiles can also be obtained from the measurements by Watzinger and Johnson (reference 4) on mixed forced- and free-convection flow in a vertical tube. Some of these measured profiles are presented in figure 3.

Equation (4), which describes the forced-convection temperature profile, is used for the temperature profile in turbulent free-convection flow. The profiles of figure 2 indicate that this assumption is reasonable. The velocity profile in free-convection flow, however, differs from the forced-flow profile by having a velocity of zero outside the boundary layer. Accordingly, equation (1) is multiplied by a function of y/δ , which brings the velocities back to the value zero at the outer edge of the boundary layer where $y=\delta$. Two simple expressions that fulfill this condition and that agree quite well with the measured values are plotted in figure 2.

FIGURE 2.—Experimental and theoretical velocity and temperature profiles for turbulent free-convection flow on a flat plate. Experimental data from reference 3.

(a) Reynolds number of 6340 (corresponding to average velocity of 4.7 cm/sec). (b) Reynolds number of 14,200 (corresponding to average velocity of 9.4 cm/sec).

FIGURE 3.—Temperature and velocity profiles in mixed forced- and free-convection flow of water in vertical tube of 50.3 millimeter (1.98 in.) diameter. Data from figure 10 of reference 4.

The velocity profile that represents the measured points somewhat better is used in the following calculations:

$$u = u_1 \left(\frac{y}{\delta} \right)^{1/7} \left(1 - \frac{y}{\delta} \right)^4 \quad (12)$$

Equation (12) is valid for values of y less than δ . For larger values of y , $u=0$. The maximum velocity u_{max} of this profile can be found by differentiating equation (12), giving

$$u_{max} = 0.537 u_1 \quad (13)$$

By use of equations (4) and (12) and the fact that $u=0$ and $\theta=0$ for distances greater than δ from the wall, the integrals in the momentum and heat-flow equations (equations (10) and (11)) become

$$\int_0^\delta u^2 dy = 0.0523 \delta u_1^2$$

$$\int_0^\delta \theta dy = 0.125 \delta \theta_w$$

$$\int_0^\delta u \theta dy = 0.0366 \delta u_1 \theta_w$$

The same value of δ was used for the velocity and temperature profiles. Calculations on forced-convection heat transfer indicate that the same value of δ for the velocity and temperature profiles can be used for fluids that have a Prandtl number close to 1 (reference 8). For very large or small Prandtl numbers in forced flow, the thickness of the temperature boundary layer is considerably smaller or larger than the thickness of the velocity boundary layer. This condition is probably true for free-convection flow also.

In order to solve boundary-layer equations (10) and (11), the laws for the shearing stress on the wall and the heat flow must be introduced. It is assumed that, in the layers very

near the wall, the conditions are similar for free- and forced-convection flow and that the same laws for the shearing stress and the heat flow that are used in forced-convection flow can therefore be used in free-convection flow. A similar assumption for the shearing stress was used by von Kármán to calculate the radial flow on a rotating disk, with satisfactory results (reference 7).

As a consequence of the preceding assumption, equations (2) and (8) will be used for free-convection flow. Very near the wall the second term in equation (12) for the free-convection-velocity profile is 1 and, therefore, the same transformation that led in forced flow from equation (2) to equation (3) can be made for free-convection flow. By introducing the evaluated integrals and equations (3) and (8), the momentum and heat-flow equations become

$$0.0523 \frac{d}{dx} (u_1^2 \delta) = 0.125 g \beta \theta_w \delta - 0.0225 u_1^2 \left(\frac{\nu}{u_1 \delta} \right)^{1/4} \quad (14)$$

$$0.0366 \frac{d}{dx} (u_1 \delta) = 0.0225 u_1 \left(\frac{\nu}{u_1 \delta} \right)^{1/4} (Pr)^{-2/3} \quad (15)$$

Equations (14) and (15) are total differential equations from which the two unknown values δ and u_1 may be determined as functions of x .

Equations (14) and (15) can be solved by introducing

$$u_1 = C_u x^m \quad (16)$$

$$\delta = C_\delta x^n \quad (17)$$

The introduction of these values transforms equations (14) and (15) into

$$0.0523 (2m+n) C_u^2 C_\delta x^{2m+n-1} = 0.125 g \beta \theta_w C_\delta x^n - 0.0225 C_u^{7/4} C_\delta^{-1/4} \nu^{1/4} x^{(7m/4)-(n/4)} \quad (18)$$

$$0.0366 (m+n) C_u C_\delta x^{m+n-1} = 0.0225 (Pr)^{-2/3} \nu^{1/4} C_u^{3/4} C_\delta^{-1/4} x^{(3m/4)-(n/4)} \quad (19)$$

Because equations (18) and (19) must be valid for any value of x , the exponents of x must be identical, that is,

$$2m+n-1 = n = \frac{7m}{4} - \frac{n}{4}$$

$$m+n-1 = \frac{3m}{4} - \frac{n}{4}$$

It can be seen that this condition is fulfilled if

$$m = \frac{1}{2} \text{ and } n = \frac{7}{10} \quad (20)$$

With these values of m and n , equation (19) can be solved for the constant C_u

$$C_u = 0.0689 \nu C_\delta^{-5} (Pr)^{-8/3} \quad (21)$$

Introducing this constant into equation (18) gives

$$C_\delta^{10} = 0.00338 \frac{\nu^2}{g \beta \theta_w} [1 + 0.494 (Pr)^{2/3}] (Pr)^{-16/3} \quad (22)$$

Introducing the Grashof number $Gr = \frac{g \beta \theta_w x^3}{\nu^2}$ gives for the velocity

$$u_1 = 1.185 \frac{\nu}{x} (Gr)^{1/2} [1 + 0.494 (Pr)^{2/3}]^{-1/2} \quad (23)$$

and for the boundary-layer thickness

$$\delta = 0.565 x (Gr)^{-1/10} (Pr)^{-8/15} [1 + 0.494 (Pr)^{2/3}]^{1/10} \quad (24)$$

More significant than the value u_1 is the maximum velocity u_{max} within the boundary layer. (See equation (13).) A Reynolds number is obtained to make this velocity dimensionless:

$$Re_{max} = \frac{u_{max} x}{\nu} = 0.636 (Gr)^{1/2} [1 + 0.494 (Pr)^{2/3}]^{-1/2} \quad (25)$$

A more significant value characterizing the thickness of the boundary layer than the value δ used up to now is the displacement thickness δ^* , which is defined for free-convection flow by the equation

$$\delta^* = \int_0^\infty \frac{u}{u_{max}} dy$$

With the use of equations (12) and (13) it is found that

$$\delta^* = 0.272 \delta$$

The displacement thickness made dimensionless by the distance x from the leading edge of the plate is therefore

$$\frac{\delta^*}{x} = 0.154 (Gr)^{-1/10} (Pr)^{-8/15} [1 + 0.494 (Pr)^{2/3}]^{1/10}$$

The heat-transfer coefficient $h = q_w / \theta_w$ at the point x on the wall is found by introducing the boundary-layer thickness δ and the velocity u_1 into equation (8). Changing to the usually presented Nusselt number $Nu = hx/k$ gives

$$Nu = 0.0295 (Gr)^{2/5} (Pr)^{7/15} [1 + 0.494 (Pr)^{2/3}]^{-2/5} \quad (26)$$

In order to compare this equation with experimental results, it is necessary to change from the local heat-transfer coefficient to the average value along the plate. By introducing the expression for the Grashof number into equation (26), it can be seen that the local heat-transfer coefficient is proportional to the power 0.2 of the distance x ($h = C_h x^{0.2}$). With the assumption that the boundary layer is turbulent from the leading edge, the average heat-transfer coefficient becomes

$$h_{av} = \frac{1}{x} \int_0^x h dx = \frac{C_h}{x} \int_0^x x^{0.2} dx = \frac{C_h}{1.2} x^{0.2} = \frac{h}{1.2} \quad (27)$$

In reality the boundary layer is first laminar and only at a certain distance from the lower edge of the plate does it become turbulent. The preceding expression for the average heat-transfer coefficient can therefore be expected to represent the true value only at Grashof numbers so high that the extent of the laminar boundary layer is small compared

with the total length x . This limit for the Grashof number seems to be near 10^{10} . For Grashof numbers higher than this value, the average Nusselt number can be calculated with equation (27); therefore,

$$Nu_{av} = 0.0246(Gr)^{2/5}(Pr)^{1/5}[1 + 0.494(Pr)^{2/3}]^{-2/5} \quad (28)$$

In order to determine to what extent the shape of the velocity profile influences the results, a calculation was made with the second velocity distribution shown in figure 2:

$$u = u_1 \left(\frac{y}{\delta} \right)^{1/7} \left(1 - \frac{y}{\delta} \right)^2 \quad (29)$$

Only the numerical constants are influenced by the change in the profile shape. The constant preceding the value $(Pr)^{2/3}$ changes from 0.494 to 0.342 in all equations. In addition, the value 0.636 changes to 0.487 in the equation for Re_{max} ; in the equation for δ^*/x the value 0.154 changes to 0.200 and in the equation for Nu_{av} the constant 0.0246 changes to 0.0198.

COMPARISON WITH EXPERIMENTS

In figure 4 the results of experiments carried out in different investigations (references 1 and 2) are plotted as the average Nusselt number Nu_{av} against the product $Gr Pr$. For the

FIGURE 4.—Average Nusselt number for free-convection flows on a vertical plate. Experimental data from references 1 and 2.

lower values of $Gr Pr$ the experimental results quite accurately fit the equation

$$Nu_{av} = 0.555(Gr Pr)^{1/4}$$

which was, with a slight adjustment of the constant, theoretically derived for laminar free-convection flow. The experimental results in the turbulent range ($Gr Pr = 10^{10}$ to 10^{12}) may be represented by the equation

$$Nu_{av} = 0.0210(Gr Pr)^{2/5} \quad (30)$$

The exponent of the Grashof number in this equation is the same as that of equation (28) derived in the previous section. When equation (28) is transformed into the form of equation (30) in such a way that the values of both equations are the same for $Pr = 0.72$, the constant of equation (28) becomes 0.0210. The heat-transfer coefficient derived with equation (12) for the velocity profile is in perfect agreement with the experimental results. Such agreement is probably a coincidence. The profile given by equation (29), which does not fit the velocity distributions measured by Griffiths and Davis in reference 3 as well as does the first profile, gives heat-transfer coefficients that are 17 percent lower than the measured values.

The values for the maximum velocity within the boundary layer and the boundary-layer-displacement thickness agree poorly with the values measured in reference 3 in the turbulent range. Heat-transfer coefficients were not measured therein on the experimental apparatus on which velocity and temperature profiles were obtained.

Whereas the velocity and temperature profile shapes as measured in reference 3 are typical of turbulent free-convection flow, the order of magnitude of these profiles appears to be in error. It can be shown that there is disagreement within the measured values themselves. The heat given off by the plate to the air stream must be carried away within the boundary layer. The measured temperature and velocity profiles as well as the measured maximum velocity and the boundary-layer thickness vary little along the plate in the turbulent range, which means that only a small part of the heat given off by the wall is found in the boundary layer. The horizontal dimension of the plate may have been too small compared with the vertical length to make the flow in the center part two-dimensional and air may have flowed into the boundary layer from the sides.

SUMMARY OF RESULTS

With the use of Kármán's approximate method, a calculation was carried out for the flow and heat transfer in the turbulent free-convection boundary layer on a vertical flat plate. The calculation used relations for the heat flow and shearing stress on the wall developed for forced turbulent flow and velocity and temperature profiles that approximate well the shapes of profiles measured by Griffiths and Davis.

A formula was derived for the heat-transfer coefficient that was in good agreement with measured values in the range of Grashof numbers from 10^{10} to 10^{12} and that can be used to extrapolate the values into the range of higher Grashof numbers. The formula is valid for Prandtl numbers that are close to 1.

The calculation also yielded formulas for the maximum velocity in the boundary layer and for the boundary-layer thickness.

REPORT 1016

EFFECT OF TUNNEL CONFIGURATION AND TESTING TECHNIQUE ON CASCADE PERFORMANCE¹

By JOHN R. ERWIN and JAMES C. EMERY

SUMMARY

An investigation has been conducted to determine the influence of aspect ratio, boundary-layer control by means of slots and porous surfaces, Reynolds number, and tunnel end-wall condition upon the performance of airfoils in cascades. A representative compressor-blade section (the NACA 65-(12)10) of aspect ratios of 1, 2, and 4 has been tested at low speeds in cascades with solid and with porous side walls. Two-dimensional flow was established in porous-wall cascades of each of the three aspect ratios tested; the flow was not two-dimensional in any of the solid-wall cascades.

Turbine-blade sections of aspect ratio 0.83 were tested in cascades with solid and porous side walls and blade sections of aspect ratio 3.33 were tested in cascades with solid walls. No particular advantage was observed in the use of porous walls for the turbine cascades tested.

INTRODUCTION

Airfoils are tested in cascades to provide fundamental information for the design of compressors and turbines. This information can be applied directly as basic data in many designs. The advantage of cascade testing lies in the relative ease and rapidity with which tests can be made, in the elimination of three-dimensional and boundary-layer effects not related to section performance, and in the much more detailed information concerning section performance which can be obtained in comparison with that obtainable from tests of rotating compressors and turbines. Cascade results have always contained inherent discrepancies, however, because the flow could not be made truly two-dimensional. These discrepancies arose from the interference and interaction of the boundary layers on the side walls with the flow about the test airfoils because of the finite aspect ratios necessarily used.

The data reported in references 1 and 2 are in some ways inconsistent and, in cross-plotting these data for design studies, irregularities appear such that the design would be indeterminant within the limits of required accuracy. These irregularities have caused much difficulty to persons attempting to interpolate or extrapolate the data for particular applications. Inconsistencies also arose from the fact that data from the Langley 5-inch cascade tunnel had always been

subject to operating technique; for example, much skill and experience were necessary in adjusting the flexible floors correctly and data that were repeatable were difficult to obtain.

The specific difficulties that have led to distrust of previously obtained cascade data are:

(1) As was pointed out in reference 3, the lift coefficient obtained by integrating the pressure-distribution plots of reference 1 did not agree with that calculated from the measured turning angle, when two-dimensional flow was assumed.

(2) The fact that the pressure rise expected to result from the measured turning angle was not obtained obviously should have an effect on the magnitude of the turning angle; therefore, some question arises as to the validity of the data in references 1 and 2. The pressure distribution is also affected in magnitude and in shape by the failure to obtain the calculated pressure rise.

(3) Compressor-blade sections of higher camber than could be satisfactorily tested in the original 5-inch cascade have been successfully used in a single-stage test blower (reference 4).

These effects are believed to be caused by the interaction of the tunnel-wall and test-blade-surface boundary layers since premature separation occurs at the juncture of the side walls and test blades and produces a large low-energy region at the exit from the cascade. This large wake acts as a restriction on the flow, higher average exit velocities result, and the flow is not two-dimensional.

Two-dimensional flow is believed to exist when the following criteria are satisfied:

(1) Equal pressures, velocities, and directions exist at different spanwise locations.

(2) The static-pressure rise across the cascade equals the value associated with the measured turning angle and wake.

(3) No regions of low-energy flow other than blade wakes exist. The blade wakes are constant in the spanwise direction.

(4) The measured force on the blades equals that associated with the measured momentum and pressure change across the cascade.

(5) The various performance values do not change with aspect ratio, number of blades, or other physical factors of the tunnel configuration.

¹ Supersedes NACA TN 2028, "Effect of Tunnel Configuration and Testing Technique on Cascade Performance" by John R. Erwin and James C. Emery, 1950.

Past attempts to establish two-dimensional flows in cascades have utilized boundary-layer removal slots on two or all of the tunnel walls upstream of the cascade, and cascades using blades of aspect ratio 4 or higher have been constructed. The present investigation was intended to determine the value of these methods and that of a method believed to be new—the use of continuous boundary-layer removal through porous surfaces from the cascade side and end walls. A representative compressor-blade section of aspect ratios of 1, 2, and 4 was tested at low speeds in cascades with solid and with porous side walls. This section was tested over a range of Reynolds number for each of these conditions. For comparison, turbine-blade sections in which the flow is characterized by a pressure drop through the test section were tested in cascades with solid and with porous side walls.

When schlieren or shadow photographs of flows through cascades are desired, the use of porous side walls would be difficult; therefore, several methods of correcting solid-wall-cascade results to the two-dimensional case have been compared and their accuracy discussed.

SYMBOLS

A	aspect ratio, span of blades divided by chord of blades
C_w	wake coefficient, coefficient of momentum difference between wake and free stream, based on entering velocity
C_N	blade normal-force coefficient based on entering velocity
$(C_N)_P$	blade normal-force coefficient obtained by integration of blade pressure distribution
$(C_N)_M$	blade normal-force coefficient calculated from measured momentum and pressure changes
q	dynamic pressure, pounds per square foot
R	Reynolds number, based on blade chord and entering air velocity
V	velocity, feet per second
α	angle of attack, angle between entering air and chord line of blade, degrees
β	inlet air angle, angle between entering air and axis, degrees
θ	turning angle, angle through which air is turned by blades, degrees
σ	solidity, chord of blade divided by gap between blades

DESCRIPTION OF TEST EQUIPMENT

The test facilities used in this investigation were the Langley 5-inch and 20-inch cascade tunnels. The 5-inch cascade test section proper uses the same design and, to a considerable extent, the same parts as the one described in reference 1. A larger settling chamber having an area of

about 25 square feet is used, however, and provides a ratio of settling-chamber area to test-section area of about 40:1. A similar settling chamber is used on the 20-inch cascade with an area ratio of only 10:1. It is believed that, if a larger area ratio were used, this cascade would yield satisfactory entrance flows and less attention to the flexible-wall curvatures and suction pressure on the upstream slots would be needed. A sketch of a vertical cross section of either tunnel is shown as figure 1. Photographs of the two tunnels are presented as figures 2 and 3.

FIGURE 1.—Vertical cross section of two-dimensional low-speed cascade tunnels.

FIGURE 2.—Langley 5-inch cascade tunnel equipped with porous walls.

The porous surface is supported by a 120-mesh screen, which is in turn supported by a sheet of perforated metal having $\frac{1}{8}$ -inch-diameter holes with $\frac{1}{4}$ inch between their centers in all directions. (See fig. 4.) This perforated sheet metal is available from steel suppliers as a standard item. A rigid frame of cellular construction is employed to carry the test airfoils and to minimize the bowing of the side walls due to the suction pressure. A number of different materials were investigated for use as porous surfaces; the results of this study are presented in a subsequent section.

The consideration that determined the particular cascade selected for detailed study was the desire to have as direct a comparison as possible with the present blading in the rotor of the 42-inch test compressor. The NACA 65-(12)10 compressor-blade section as used in this compressor has an inlet angle of 60° at the mean diameter and a solidity of 1.182 and is fairly typical of axial-flow compressor rotors. Because of the geometry of the cascade tunnel used, the sections were tested at a solidity of 1. This cascade has a relatively high static-pressure rise and high blade normal-force coefficient, conditions which make cascade testing difficult.

In addition, some data obtained at the less severe condition of 45° inlet angle are included to provide a more complete picture of the problem and of the results obtained.

The cascade of airfoils selected for detailed study was tested at low speed in the following tunnel configurations:

- (1) 5-inch, blade aspect ratio 1, solid-wall cascade
- (2) 5-inch, blade aspect ratio 1, porous-wall cascade
- (3) 5-inch, blade aspect ratio 2, solid-wall cascade
- (4) 5-inch, blade aspect ratio 2, porous-wall cascade
- (5) 20-inch, blade aspect ratio 4, solid-wall cascade
- (6) 20-inch, blade aspect ratio 4, porous-wall cascade

Turning-angle, pressure-rise, pressure-distribution, and wake-survey measurements were taken. For comparison purposes, results obtained by using a 42-inch-tip-diameter test compressor and a 28-inch-tip-diameter test compressor are presented. All but wake-survey measurements were taken in the 42-inch test compressor described in reference 5. Turning-angle and pressure-rise measurements were obtained with the 28-inch test compressor (reference 4).

The testing procedures used in this investigation were the same as those reported in reference 1. Most of the tests were made with a fixed entrance velocity of about 95 feet per second and with blades of 5-inch chord. A few tests at other speeds were made to vary the Reynolds number. Tests on blades of aspect ratio 2 used airfoils of $2\frac{1}{2}$ -inch chords. With the exception of tests run to determine proper end conditions, cascades of seven blades were used throughout.

In order to expedite plotting of test pressure-distribution results, a constant entrance dynamic pressure is normally used in cascade testing at the Langley Laboratory. Manometers scaled with values of q_1/q_2 are used so that no computing is required to make these plots. It is therefore convenient to obtain force coefficients on the basis of the entering dynamic pressures. All coefficients presented herein are so calculated.

FIGURE 3.—Langley 20-inch cascade tunnel equipped with porous walls.

FIGURE 4.—Sketch showing construction of porous wall.

The static-pressure rise across the test section can be controlled to a considerable extent by the quantity of flow drawn through the porous walls. The pressure rise corresponding to two-dimensional flow through the observed turning angle, when allowance for effective passage-area reduction due to the observed wake is made, could be established by this means. A chart of pressure rise or, more specifically, of q_2/q_1 , was prepared for a range of turning angle and wake width for the test inlet air angle and solidity (fig. 5). The effect of the blade wake on the exit velocity was taken into account by measuring the exit velocities and averaging the values for a few test points. A factor, dependent upon the wake width, was so obtained and was applied in computing values of q_2/q_1 for other conditions. This factor assumes that wakes of similar width will restrict the exit flow similarly. The validity of the curves was later confirmed by detailed velocity calculations for many tests. For all tests in which continuous boundary-layer removal was used, the pressure rise across the cascade was set by reference to the chart. Of course, this method was not applied to the series in which the pressure rise was intentionally made different from the two-dimensional value in order to examine the resulting effects.

RESULTS AND DISCUSSION

GENERAL

The investigations reported in references 1 and 2 used blades of aspect ratio 1. The results obtained, although providing useful information, failed to satisfy the criteria of two-dimensional flow. The Langley 20-inch cascade tunnel was constructed to permit blade models of aspect ratio 4 to be

FIGURE 5.—Relation between dynamic-pressure ratio across cascade to turning angle. $\beta=60^\circ$.

tested without reduction in blade chord or test Reynolds number. The results for blades of aspect ratio 4 indicated that the static-pressure rise obtained did not agree with that calculated by using the measured values of turning angle and by assuming two-dimensional flow, even though correction was made for the blade wake measured at midspan. Further, the turning angles observed were quite different from the turning-angle values obtained in the test compressors. Correcting the data to account for the constriction due to separation near the walls failed to produce corrected turning angles in agreement with the values measured in the test compressors. When the data for the 5-inch blades of aspect ratio 1, which agree with the data for the test compressors, were so corrected, however, the resultant values were lower than test-compressor results. The values for the normal-force coefficient for the tests on blades of aspect ratio 4 appear to be in closer agreement with the values calculated on a basis of two-dimensional momentum and pressure changes when they are plotted with corrected turning angles than when the measured turning-angle values are used, but since the slopes of C_N against θ_c differ, the results are in question.

Thus it appears that cascades of aspect ratio 4 do not yield directly usable information even when axial-velocity corrections are applied. Because the blades are not operating under pressure-rise, turning-angle, and angle-of-attack conditions that represent the two-dimensional case, cascades of neither $A=1$ nor $A=4$ provide the conditions sought. Furthermore, large air supplies are required for high-aspect-ratio cascades, particularly for high-speed tests. For these reasons, attempts were made to devise methods that would provide two-dimensional flows in cascades using blades of low aspect ratio.

The interference and interaction of the tunnel-side-wall boundary layers with the boundary layers of the test airfoils were believed to be the reason for the flow not being two-dimensional. If the side-wall boundary layers could be removed continuously through the side walls, two-dimensional flow conditions could perhaps be established. In order to examine this possibility, the Langley 5-inch and 20-inch cascade tunnels were modified by replacing the test-section side walls with a frame supporting a perforated metal sheet and a porous material was attached to this perforated sheet. As illustrated in figure 2, a suction chamber connected to a blower was provided on the outside of the test section, and a part of the flow was drawn through the side wall. First tests using this system indicated considerable promise but also indicated that the material used for the porous surface affected the quantity of flow that had to be removed to establish two-dimensional conditions. For this reason, a search for suitable porous materials was initiated, and several materials were tested in the 5-inch cascade.

Other elements of the tunnel configuration that affect the character of the flow into the cascade are the entrance-cone shape, the type, location, and number of the wall slots, and the treatment of the end wall. Only one modification of the circular-arc entrance-cone shape used on both tunnels was tried: The 20-inch-tunnel fairings were replaced with fairings of parabolic curvature in an attempt to eliminate the unfavorable pressure gradient that existed with the circular-arc

cone. No measurable reduction of end-wall boundary-layer thickness was observed, however.

TEST-SECTION CONDITIONS FOR TWO-DIMENSIONAL FLOWS

Porous materials.—Ideally, it would be desirable to employ permeable surfaces having varying porosity in order to distribute the boundary-layer removal in a manner related to the local boundary-layer thickness. No scheme that would be practical for a series of tests was evolved to accomplish this result. In a general way, a surface of uniform porosity accomplishes the desired result, for, where the pressure recovery has been the greatest, the quantity flowing through the surface will be greatest. The regions of highest pressure are unfortunately not necessarily regions where the boundary layer is thickest or most likely to separate; therefore, a surface of uniform porosity is not ideal for compressor-cascade side walls. The surface porosity for these low-speed compressor-blade tests was determined by the requirement that the suction-chamber pressure be lower than the lowest pressure on the test airfoils. In this condition, the flow through the wall surface was everywhere outward from the test section to the suction chamber.

The first tunnel configuration using porous walls had a very heavy canvas as the surface. Because of the appreciable roughness of this material, a very large quantity of the main flow had to be removed through the canvas in order to obtain the pressure rise associated with the measured turning angle. Although a direct quantity measurement was not made, an estimate based on the suction pressure used would be that an air quantity of from 20 to 25 percent of the entering flow was removed through the walls. A medium-weight broadcloth material having a fairly smooth surface on one side was next tried. The quantity of air removed was 10.3 percent of the entering flow; this amount includes some leakage flow. Broadcloth surfaces were used for most of the tests reported herein.

One test using 2-ounce nylon sailcloth was run. This material appears to have desirable smoothness, strength, and abrasion-resistance properties, but the sample used was too closely woven for the conditions of the test. A flow volume sufficiently large to produce the required pressure rise through the cascade could not be removed with the existing suction blower. A very light parachute silk was also tried, but with the opposite result—the porosity was too great, and several layers would have been required to obtain a satisfactory permeable surface. This arrangement was considered impractical for routine operations requiring many tunnel changes.

Several tests were run with a metal screen, made by electroplating, as the porous surface. This material, a copper-nickel alloy, has a very smooth, uniform surface, which is much smoother than wire screen of similar mesh (100), and is without the fuzz of cloth. The sample used had 16-percent open area. One or two layers of broadcloth backing were employed to produce the necessary resistance. A significant reduction in the porous-wall air removal was measured in the tests; the air removal dropped from the previous value of 10.3 to 4.5 percent of the main flow. Better agreement resulted between normal-force coefficients

calculated from measured blade pressure distributions and those calculated by using the momentum equation. The electroplated metal screen was rather expensive, however. A porous surface formed by hammering copper or bronze screen was found to be very practical and quickly made. This technique is attributed to Mr. P. K. Pierpont of the Langley Full-Scale Research Division. By varying the number of hammering operations (each followed by torch annealing), a material of required porosity could be obtained. A screen successfully used over a wide range of test conditions had initial wire diameter of 0.014 inch, 30 mesh, and was hammered to a sheet thickness of 0.009 inch. The normal flow velocity plotted against pressure drop for this material is presented in figure 6.

A commercially available material, twill dutch double weave filter cloth, usually woven of monel wire, having 250 fill wires of 0.008-inch diameter per inch and 30 warp wires of 0.010-inch diameter per inch was found to be very satisfactory when commercially calendered from the as-woven thickness of 0.027 inch to 0.018 inch. This filter cloth permitted normal velocities at a given pressure drop similar to those presented in figure 6 for the hammered screen.

No comparative tests were run in the 20-inch tunnel, but it is believed that a similar reduction in porous-wall air removal could have been achieved; however, a typical value for this removal in the 20-inch tunnel is 2.9 percent when broadcloth is used. This percentage was so small that attempts to reduce the amount seemed unnecessary.

Slot configurations.—A series of runs was made with several combinations of tunnel side-wall and end-wall slots in order to produce uniform entering flows and to reduce porous-wall suction-flow quantity. The possibility of using flush side-wall slots was considered, since flush side slots would eliminate the width change in the end plates and would increase the ease and decrease the time of operation. The tests were made by using existing sharp-edge protruding slots with and without fairings in order to vary the configuration and therefore these slots do not represent optimum slot shapes. The side-wall slots were closed by fairings extending

FIGURE 6.—Velocity through two porous materials as a function of the pressure drop.

from the entrance cone to the slot; these fairings reduced the tunnel width to a constant 5 inches. An increase of 2 percent of the main flow or 21 percent of the permeable-wall flow was required to establish the desired cascade pressure rise.

The fairing was then moved $\frac{1}{4}$ inch upstream to produce a flush slot, and 10.5 percent of the main flow was drawn through the porous wall when 8.8 percent was removed through the flush slot. An increase in slot suction pressure, which raised the slot flow to 11.4 percent, decreased the required porous-wall flow only slightly to 10.3 percent of the main flow. Increasing the flush-slot width to $\frac{1}{4}$ inch had a detrimental effect on the required flow through the cloth wall. A different slot shape similar to that recommended in reference 6 might have improved the performance, but this possibility has not yet been investigated. Flush slots parallel to the cascade might be expected to deflect the entering flow at inlet air angles other than zero. In these tests, however, this effect was not measurable when the static-pressure drop through the slot was less than one-half the dynamic pressure entering the cascade. For the usual range of cascade inlet angles, no greater static-pressure drop than one-half the entering dynamic pressure has been found necessary.

The few tests run to determine the end-wall slot configuration indicated the same trends as the side slots. The protruding slots were slightly more effective than flush slots, but only an insignificant reduction in air removal was gained over the sealed or no-slot condition. However, when seven blades were used with the end blades serving as the cascade boundary, boundary-layer removal was necessary. Without the end slots, separated turbulent flow occurred over the end blades, and uniform entering conditions for the cascade apparently could not be established.

Figure 7 shows the boundary-layer profile measured at several stations about 1 chord upstream of the cascade. The origin of each of the small plots is placed at the survey point. It is evident that the protruding slot produces a clean flow at these locations.

For conditions of large inlet air angles, the side-wall length from the entrance cone to the slot varies considerably from one end of the cascade to the other (fig. 1), and the boundary thickness varies in a similar manner. With a fixed slot width and with essentially constant slot-suction-chamber

FIGURE 7.—Total-pressure loss in percent of entering dynamic pressure, with and without boundary-layer slot. Survey stations located at origins of small coordinate axes.

pressure, asymmetrical flow in the test section could result from the difference in boundary-layer thickness. No difficulties encountered during the investigation reported herein were traced to this source, however. When testing at $\beta=70^\circ$, uniform flow entering the test section could not be satisfactorily obtained with the slot configurations previously described. Inlet-angle plates having a construction similar to the porous-wall test section were installed in place of the solid plates normally used. When a small quantity of flow was drawn through the porous surface of the inlet-angle plates, uniform flow entering the test section was readily established at $\beta=70^\circ$.

End conditions.—In order to study the effect of the end gap on the behavior of the main flow, a few tests using five blades were run with varying end gaps. A blade equipped with orifices was placed nearest the end walls. As indicated in figure 8, in the case of the half-gap end spacing, the last blade did not carry lift equal to that of the central blade. When the end spacing was increased to a whole gap, the lift on the end blade increased considerably, although not up to the value of lift on the central airfoil. The important result, however, is that the change of end gap had no measurable effect on the performance of the central blade. The pressure distribution, turning angle, and drag coefficient remained as before.

Other investigators have used the end blades in the cascade as the boundary (reference 7). In order to examine the possibilities of this method, two extra blades were installed in the 5-inch cascade tunnel. Runs were first made with the end walls sealed to the end blades approximately at their stagna-

(a) Approximate half-gap end spacing.
(b) Approximate whole-gap end spacing.

FIGURE 8.—Effect of end gap on the pressure distribution measured on the end blade.

tion points. This system provided too few variables, and proper entering conditions could not be established; in addition, the end passages exhibited stalling and fluctuating flows. The end walls were moved outward about $\frac{1}{2}$ inch for the subsequent test, and a gap between the flexible end walls and the end blades resulted. Attempts were made to control the entering static pressure and direction of flow by bending the end walls. Considerable stalling continued to occur, however, apparently because of the thick end-wall boundary layer. To investigate this possibility a $\frac{3}{16}$ -inch protruding slot was built into the upper and lower end walls 1 chord ahead of the test blades. These slots were connected by ducts to an exhaustor. Satisfactory control of entering conditions was possible by bending the flexible surfaces. Some operating time is eliminated with this system since it is not necessary to set the end wall exactly in the direction of the exit flow, and less skill and time are required in adjusting the entering conditions. However, the flow about the central blade appeared to be the same as that for the other two satisfactory tunnel configurations.

The number of blades required in a cascade appears to be an inverse function of the amount of time and care employed in establishing the end conditions. With the flexible end walls used in the cascades described herein, little difference in performance was noticed between similar configurations of five or seven blades. In a setup where end-wall adjustments are not readily made or where running time is limited to a few minutes, significant differences in the performance might be observed.

In tests of airfoils more highly cambered than the NACA 65-(12)10 section reported herein, continuous boundary-layer removal on the convex end wall has been necessary in order to prevent separation from this wall and to permit uniform exit flow from the cascade. A porous surface beginning at the end-wall slot, about 1 chord upstream of the blades, was extended through the cascade to about 1 chord downstream of the blades. Provision was made for flexing this end wall to the desired curvatures. Although continuous boundary-layer removal might also be desirable for the concave end wall, the additional complexity is undesirable. A thin sheet-brass end wall has been found to provide satisfactory flows at an inlet angle of 60° and at a turning angle of 30° , which is a rather severe case.

COMPARISON OF CASCADE AND TEST-BLOWER RESULTS

Turning angle and static-pressure rise.—Results for the several cascades and test blowers investigated are given in figures 9 and 10 as plots of turning angle against angle of attack. All test airfoils are the NACA 65-(12)10 section. All inlet angles are 60° and all solidities are unity, with the single exception of the 42-inch-diameter test compressor, in which a mean diameter solidity of 1.182 existed and in which the inlet angle increased with angle of attack so that $\beta=60^\circ$ occurred at $\alpha=14^\circ$. Turning-angle corrections obtained from reference 2 for varying inlet angle in the 42-inch compressor are presented. Because the rotor-blade solidity was 1.182, the turning angles measured in the 42-inch compressor were predicted to be about 0.4° higher than in the 28-inch test blower or cascades of solidity 1.

FIGURE 9.—Effect of aspect ratio on turning angle for solid-wall cascades. A median curve (dashed line) obtained from figure 10 is presented for comparison.

FIGURE 10.—Effect of aspect ratio on turning angle for porous-wall cascades. Results from two test compressors are also given. Turning-angle corrections for varying inlet air angles of the 42-inch compressor are indicated. For the 42-inch compressor, $\beta=56^\circ$ at $\alpha=10^\circ$ and $\beta=64^\circ$ at $\alpha=18^\circ$.

If the results of the solid-wall cascade tests are compared, an increasing turning angle with increasing aspect ratio is very evident. The results from porous cascades and test blowers agree with the data from the solid-wall cascade of aspect ratio 1. This behavior is believed to be due to counteracting effects. The velocities induced by the trailing vortices due to reduced lift in the tunnel-wall boundary layers and the movement of the wall boundary layer onto the suction surface of the airfoils have an over-all result of reducing the blade lift and hence the net turning angle. A factor having an opposite effect is the increase of axial velocity resulting from thickened wall boundary layers (see

reference 3). That this effect exists is evident during operation of the porous-wall cascades: As the porous-wall flow is increased and the pressure rise across the cascade is increased, a measurable reduction in turning angle takes place. Figure 11 shows this effect for the cascade with blades of aspect ratio 4.

In a recent paper (reference 8), Hausmann has presented an analysis of the simplified trailing-vortex problem. In the rather severe case calculated, the indication is that the turning angle would be increased because of the downwash associated with the trailing vortices. The opposite effect is predicted by Carter and Cohen in reference 9. A discussion of these counteracting effects is presented in a subsequent section, with the conclusion that no method is now available to explain satisfactorily the flows observed in the solid-wall cascades.

The solid-wall cascades studied failed to produce the pressure rise associated with the measured turning angles (fig. 12). At low aspect ratio the three-dimensional effects predominated, and low turning angles were observed. With higher aspect ratios, the induced effects were of smaller magnitude, and more turning of the flow resulted. To approach two-dimensional flows in solid-wall cascades, aspect ratios much greater than 4 must be used.

Satisfactory agreement of θ with α and q_2/q_1 with θ was obtained between porous-wall cascades of aspect ratios of

FIGURE 11.—Variation of turning angle with variation in pressure rise as obtained in the porous-wall cascade of aspect ratio 4. The calculated value for the measured turning angle of 20° ($\Delta\theta = 0^\circ$) is $\frac{q_2}{q_1} = 0.450$; the value measured with no flow through the porous walls was $\frac{q_2}{q_1} = 0.630$. $\alpha = 15.1^\circ$.

FIGURE 12.—Dynamic-pressure ratio as measured in the various tunnel configurations tested. The solid-line curve indicates the calculated value of q_2/q_1 .

1, 2, and 4 and two test blowers at their mean diameters. The porous-wall cascades appear to satisfy these criteria of two-dimensionality.

Passage wake surveys.—An examination of the flow downstream of the cascade was made in order to determine how much of the flow was homogeneous. Total-pressure surveys of the test cascade were made in the solid-wall and porous-wall configurations with blades of aspect ratio 1 at an angle of attack of 15.1° . The results are presented in figure 13. In the solid-wall case, a large region of low-energy air, which had its core originating at the junction between the convex surfaces of the test airfoil and the tunnel wall, was observed. In reference 9, a similar plot is presented for a cascade of aspect ratio 2 in which similar results are indicated. The percentage of the flow area affected is less, however, and a short region of uniform flow appears in the center of the tunnel.

The porous-wall configuration had only a relatively small region of loss greater than that of the wake of the test blades. The portion of the wake unaffected by the spread near the wall was 80 percent of the tunnel width. The total-pressure-loss values in this "two-dimensional" wake were lower and of smaller extent than in the solid-wall test.

A comparison of these plots illustrates clearly how continuous removal of the wall boundary layers alters the static-pressure rise across a compressor cascade. With solid walls, the large low-energy regions act to constrict the main flow and so reduce the effective flow area, so that an increase in the main exit flow velocity results. With permeable walls, since the effective exit flow area is much larger, the exit velocity is smaller and the static-pressure rise is higher.

Comparison of normal-force coefficients.—One of the important criteria for two-dimensional flow is that the value for the force on the blades determined by calculation of the momentum and pressure changes associated with the meas-

FIGURE 13.—Comparison of downstream total-pressure-loss contours obtained in the Langley 5-inch cascade tunnel with solid walls and with porous walls. $A=1$; $\sigma=1$; $\alpha=15.1^\circ$.

ured turning angle be equal to the force as determined by integration of the surface pressures. The ability of the configurations used to satisfy this criterion is illustrated in figure 14. The solid-wall cascade of aspect ratio 1 fails badly. The solid-wall cascade of aspect ratio 4 is better but the normal-force coefficient obtained from pressure distributions is from 7 to 15 percent low. The porous-wall cascades are clearly superior on this count, because reasonable correlation between $(C_N)_P$ and $(C_N)_M$ is indicated over the usual operating range.

Figure 15 shows that good agreement was obtained between $(C_N)_P$ and $(C_N)_M$ with the porous-wall cascade of aspect ratio 1 at the lower-pressure-rise case of $\beta=45^\circ$. No tests at lower than 45° inlet angle were included in this investigation, but it is believed that satisfaction of all the criteria of two-dimensionality would be obtained.

The pressure rise across the cascade has an effect on the force normal to the blade. In order to calculate this force, the pressure rise must be known or assumed. The calculated normal-force-coefficient curves of figures 14 and 15 were prepared by using the pressure rise measured in the porous-wall cascades. As previously noted, the values of q_2/q_1 are controllable with continuous boundary-layer removal and were adjusted to correspond to the observed turning angle with allowance for the observed wake. The calculated values of C_N presented are therefore believed to be representative of two-dimensional flow and the most logical basis for comparison.

FIGURE 14.—Comparison of normal-force coefficient obtained in various cascades. Solid-line curve indicates calculated values of C_N .

An interesting comparison is that of the pressure-distribution normal-force coefficients obtained with the 42-inch-diameter test compressor, the values calculated for the observed turning angles and the values obtained in solid-wall cascade of aspect ratio 1. This cascade might be expected to produce effects similar to the blower, if the physical similarity were the determining factor, since the test compressor has blades of aspect ratio of about 1, solid "walls," and a solidity of 1.182. The values of σC_N presented in figure 16 illustrate that the effects are not similar. At the mean diameter, the σC_N values of the test compressor match the values calculated for the measured turning angles within the limits of the measuring accuracy, but the values for the solid-wall cascade of aspect ratio 1 are greatly different.

The excellent agreement between the test compressors and the porous-wall cascades on turning-angle (θ against α), normal-force-coefficient ($(C_N)_P$ and $(C_N)_M$ against θ), and pressure-rise (q_2/q_1 against θ) relations probably results from the relatively greater energy of the boundary layers in the compressors compared with the energy of the boundary layer in the cascade tunnels. This energy difference, which is due to greater relative velocities between the boundary layer and the running blades in the compressors as compared with the stationary blades in the cascade, is discussed in reference 3. The excellent agreement obtained illustrates that two-dimensional cascade data can be used directly in the design of axial-flow compressors.

Spanwise pressures.—One of the characteristics of a flow constant in the spanwise direction is that equal pressures exist at one chordwise position at different spanwise locations. In order to examine the ability of the various setups to meet this requirement, airfoils having static-pressure orifices located $\frac{1}{2}$ inch from the tunnel wall as well as at the usual center-line location were constructed. NACA

FIGURE 15.—Comparison of normal-force coefficient obtained by integration of blade pressure distribution and by momentum-change calculations. $\beta=45^\circ$; $\sigma=1$; porous walls.

65-(12)10 compressor blades of aspect ratio 1 were tested at $\beta=60^\circ$, with a solidity of 1, with solid and with porous walls. In the solid-wall case (fig. 17) the pressures near the wall are quite different from those along the tunnel center at the various chordwise stations. In addition, the normal-force coefficient obtained by integrating the center-line diagram is significantly lower than that calculated from the measured turning angle. This fact, coupled with the dif-

FIGURE 16.—Comparison of normal-force coefficient measured in the 42-inch-diameter test blower with that measured in the solid-wall cascade of $A=1$. The solid curve is calculated from measured turning angle, the appropriate inlet angle being considered.

FIGURE 17.—Pressure distributions at two spanwise locations in the 5-inch solid-wall cascade of aspect ratio 1. $\alpha=14.1^\circ$.

ference between the measured and calculated exit velocities, suggests that significant differences in the pressure distribution would occur either in the ideal two-dimensional case or in a compressor (the calculated pressure rise has been obtained in several test compressors). This possibility was discussed in reference 3.

Pressure distributions similar to those for the solid-wall condition are presented in figure 18 for the porous-wall condition. Excellent agreement is obtained between the two diagrams. The normal-force coefficients obtained by integration and by calculation agree within the limits of experimental error.

For purposes of comparison, the center-line pressure distributions of figures 17 and 18 have been replotted in figure 19. Although the angle of attack and turning angle were similar in the solid-wall test, it is clear that the total area is considerably less and that the pressure distributions differ from each other in such a manner that it would be difficult, if not impossible, to devise a method for correcting the solid-wall test results to agree with those which would result in a two-dimensional flow.

Similar agreement was obtained in porous-wall tests at an inlet air angle of 60° with a cascade of aspect ratio 4 (fig. 20) over the test range of angle of attack. It is therefore believed that a reasonably close approach to two-dimensional flow was obtained with continuous removal of the tunnel-wall boundary layers.

EFFECT OF REYNOLDS NUMBER

A set of 2.5-inch-chord airfoils was constructed to permit cascade tests with blades of aspect ratio 2. At the usual test velocity of about 95 feet per second, the Reynolds number of this cascade would be 123,000, a value presumably well above the critical range at which scale effects occur (usually taken to be about 100,000 for typical axial-flow compressors). Because of the low turbulence level of the Langley 5-inch cascade tunnel, laminar separation existed, and very poor performance was observed. (Velocity variation was 0.0004 of stream velocity; however, in both tunnels the turbulence factor varied somewhat with the air velocity.) A series of tests was therefore run in an attempt to define the critical Reynolds number for the test cascade in several tunnel configurations.

The 2.5-inch-chord blades in the original smooth condition were tested at several values of R by increasing the test entrance velocity. In figure 21, a leveling of the turning-angle and drag-coefficient curves around values of $R=250,000$ is indicated for these tests. Because the tunnel motor and blower appeared to be operating at speeds above a safe limit, attempts were made to simulate higher effective values of R by introducing turbulence into the air stream and by using airfoils roughened by a strip of masking tape at the leading edge. Figure 22 indicates that a turning-angle performance indicative of higher effective Reynolds number can be obtained by the use of roughness. Some difficulty was encountered in introducing turbulence to the test air stream and still maintaining uniform entering-flow conditions; therefore, the results are not presented herein. However, qualitatively, the expected effect was observed.

FIGURE 18.—Pressure distributions at two spanwise locations in the 5-inch porous-wall cascade of aspect ratio 1. $\alpha=14.1^\circ$.

FIGURE 19.—Comparison of test-airfoil surface pressure distributions measured along tunnel center line with solid and with porous walls. $\alpha=14.1^\circ$.

FIGURE 20.—Comparison of pressure distributions at two spanwise locations taken in the porous-wall cascade of aspect ratio 4, at 60° inlet angle, and with a solidity of 1. $\alpha=9^\circ$.

FIGURE 21.—Effect of Reynolds number on cascade performance. $\alpha=15.1^\circ$.

FIGURE 22.—Effect of roughness on cascade performance over a range of Reynolds numbers. Tests were made in 5-inch solid-wall cascade of aspect ratio 2.

To make certain that values of R above 250,000 would produce only insignificant changes in performance, a set of 5-inch-chord airfoils were rerun in the 5-inch cascade with solid walls at the usual test velocities and at higher values. These results are included in figure 21. Since the aspect ratio of the blades used in these tests was unity, the turning-angle values are not directly comparable with the results of the 2.5-inch-chord tests. The indication is that the critical Reynolds number is about 250,000.

Hot-wire anemometer measurements in the 20-inch tunnel indicated that the turbulence factor of this tunnel was about ten times that of the 5-inch tunnel. To obtain further information on Reynolds number effects, the test cascade was rerun in the 20-inch tunnel. Entering speeds above and below the usual value were used. These results are also included in figure 21. In the Reynolds number range between 160,000 and 250,000 the turning-angle values for the porous-wall cascades of $A=1$ and $A=4$ vary less with R than do the values for solid-wall cascades of $A=2$. Apparently, continuous removal of the side-wall boundary layer makes a compressor cascade less sensitive to Reynolds number changes.

A large variation in the value of the measured wake coefficient is noted at $R=250,000$. The section drag for the solid-wall cascade of $A=1$ is influenced by the blade-wall junction losses, as was shown in figure 13. The wake coefficients of the test airfoils of $A=2$ in the solid-wall cascade and $A=1$ in the porous-wall cascade are believed to be greater than those of the airfoils with $A=4$ because of the greater turbulence and higher effective Reynolds number in the 20-inch tunnel. This trend is evident in figure 23, in which a plot of C_w against α is presented for several tunnel configurations. The scatter of the C_w values suggests the order of accuracy of this measurement.

Data taken at angles of attack other than 15.1° indicate a large change in the values of $d\theta/d\alpha$ with R (fig. 24). Most of these data were obtained with the solid-wall cascade with blades of $A=2$ over only a 4° range of α ; however, a more complete α range was run in a porous-wall cascade with blades of $A=2$ at $R=190,000$ and $176,000$. The points presented in figure 24 are not to be considered final, but they do provide an indication of the trend to be expected.

The decrease of $d\theta/d\alpha$ with R is believed to be related to the pressure gradients near the leading edge of the convex surface of the test airfoils and to the extent of the laminar separation. At lower angles of attack, the pressure recovery in the forward 35 to 40 percent chord is small (fig. 20) and laminar flow can exist for some distance so that a relatively thick laminar boundary layer results. Farther downstream a rapid pressure rise occurs and, at low Reynolds numbers, a severe laminar separation takes place and low lift and low turning angles result. The fact that severe separation occurs is indicated by the high C_w values measured at low Reynolds numbers (fig. 21). At higher angles of attack, the region favorable to a laminar boundary layer is reduced, so that when laminar separation takes place the separation is of lesser extent. (In some cases, particularly at higher Reynolds numbers, the flow may reattach to the surface.) Thus,

FIGURE 23.—Wake coefficient of the NACA 65-(12)10 airfoils at $\beta=60^\circ$ and $\sigma=1$ for various angles of attack.

FIGURE 24.—Effect of Reynolds number on curve of $\frac{d\theta}{d\alpha}$.

as the angle of attack is increased, a disproportionate increase in turning angle occurs at low Reynolds numbers. At higher Reynolds numbers, laminar separation is less likely to occur so that these effects are less pronounced and a lower value of $d\theta/d\alpha$ results.

Attempts were made to verify the apparently reduced effect of Reynolds number on porous-wall cascades of aspect ratios 1 and 4 by testing the 2.5-inch-chord airfoils of $A=2$ with permeable walls. With the exhausting equipment available, it was not possible to establish the desired flow conditions at Reynolds numbers above 190,000. At this value, a turning angle of 19.2° was measured at 15.1° angle of attack, and $d\theta/d\alpha$ equalled 0.90. These results agree with the previously recorded data.

COMPARISON OF SEVERAL METHODS OF CORRECTING TURNING ANGLES TO THE TWO-DIMENSIONAL CASE

There are many situations in which it would be desirable to use solid-wall cascades if suitable means for correcting the results were available, as, for example, when schlieren photographs of the flow are desired. Several methods for converting cascade and compressor results that are not two-dimensional to the two-dimensional case were applied to the data from the solid-wall cascade with blades of $A=4$. One method is based on the discussion in reference 3, in which the exit axial velocity is made equal to the inlet axial velocity. The entrance inlet angle and angle of attack are assumed to be unaffected by the exit flow (fig. 25(a)). A second

FIGURE 25.—Velocity diagrams illustrating several correction methods.

method, based on a discussion in reference 10, suggests that the exit axial velocity be adjusted by one-half the difference between inlet and exit values and the corrected turning angle be the difference between the actual inlet vector and the adjusted exit vector (fig. 25(b)). A third method is to average the inlet and exit axial velocities and then to reduce the averaged axial velocity by one-half the axial-velocity increment due to the wake to obtain the inlet axial velocity. The exit axial velocity would be greater than the average value by one-half the wake increment (fig. 25(c)). In all these methods, the change in the tangential velocity is assumed to be unaffected by the change in axial velocity. This assumption may not be valid.

The turning angles measured in the solid-wall cascade of $A=4$ have been corrected by these three methods, and the results are presented in figure 26. The turning angles measured in the solid-wall cascade of $A=1$, which were in good agreement with test-blower and porous-wall-cascade results as indicated in figure 9, are included in figure 26. Corrected values obtained by the wake-allowance method (method III), which gave the smallest change for a given axial-velocity increase, are also included for the $A=1$ solid-wall case. The turning angles for the $A=4$ case as measured were 2° to 4° higher than the median values of figure 10. The second and third methods reduced these differences to about one-half. The first method yielded results in better agreement with median curve, but the corrected values tended to be low, with a maximum difference of about 1° .

The wake-allowance method was applied to the data from the solid-wall cascade with blades of $A=1$. The corrected turning angles appear 2° to 3° below the measured data.

FIGURE 26.—Comparison of turning angles measured in the solid-wall cascades of $A=1$ and $A=4$ with values corrected by several methods.

(or the median curve) if this method is used and would be even lower if the other methods were used. Since the corrected turning angles for blades of $A=4$ tend to be too high and the values for blades of $A=1$ too low, the conclusion might be drawn that some combination of test aspect ratio and correction method could be obtained that would make possible the adjustment of cascade data that are not two-dimensional to the two-dimensional case. That such a combination would yield satisfactory results over the useful range of inlet angles, solidities, and cambers seems unlikely. Consideration of correction attempts for aspect ratios 1 and 4 indicates that a single simple method of adjusting measured values for observed axial-velocity changes is not likely to be found. Apparently factors other than the increase or decrease of axial velocity through the cascade must be taken into account. Undoubtedly one of these other factors is the effect of the flow induced by the trailing vortices. The method of reference 9 was used to estimate the magnitude of these effects in the solid-wall cascades of $A=1$ and $A=4$, for a measured turning angle of 20° . The turning angle in the cascade of $A=1$ is decreased about 2° by the induced flow, whereas the turning angle for the blade of $A=4$ is reduced by 1.7° . Adding 2° to the corrected turning angles in figure 26 would bring the $A=1$ results into closer agreement with the median curve. Adding 1.7° to the $A=4$ results, however, would cause greater disagreement between the values corrected by any of the three methods used and the median curve of figure 10.

The values of normal-force coefficient obtained by integrating the pressure distribution about the test airfoils have been replotted with the turning angles corrected by three methods (fig. 27). The corrected $(C_N)_P$ curves intersect the theoretical curve within the test range. The $(C_N)_P$ curve plotted against measured values of θ did not intersect the theoretical curve (fig. 14). Thus the axial-velocity adjustment methods used might be considered to improve the agreement between measured and calculated normal-force coefficients, but, because the slopes are quite different, only little improvement is gained. If the induced flows were taken into account by the relations of reference 9, the various values of $dC_N/d\theta_c$ would be in less agreement with the theoretical values, because the reduction of turning angle due to the trailing vortices increases with C_N . Thus no methods are at hand to explain the observed flows in the solid-wall cascades.

TURBINE-BLADE TESTS

A turbine blade designed to operate at $\beta=30^\circ$ with about 85° turning angle, a pressure-drop, reaction condition, was tested in the 5-inch tunnel in cascades of $A=0.83$ and in the 20-inch tunnel in cascades of $A=3.33$; solid walls were used. The curves of α against θ are presented in figure 28. Little difference other than experimental scatter is noted. Blade-surface static-pressure measurements taken along the tunnel center line are shown in figure 29. Greater differences than can be accounted for by inaccuracies of measurement existed, but general agreement was obtained. Tuft surveys indicated a collecting of low-energy flow at the juncture of

FIGURE 27.—Comparison of normal-force coefficients obtained in the solid-wall cascade of $A=4$ when plotted against the measured turning angles and the turning angles corrected by three methods.

FIGURE 28.—Variation of turning angle with angle of attack for one turbine-blade section tested at aspect ratios of 0.83 and 3.33.

the convex surface of the test blades and the tunnel side walls. In these tests, even at the lower aspect ratio, this condition seemed to have little effect on the test results. It is therefore believed that, with usual pressure-drop cascades, as with reaction turbine blades, nozzles, and guide vanes, useful results can be obtained with cascades of low aspect ratio.

Another reaction turbine section designed for $\theta=105^\circ$ at $\beta=45^\circ$ was tested in the 5-inch tunnel in cascades of $A=0.83$ with solid and with porous walls. Since the dynamic pressure

FIGURE 29.—Comparison of surface pressure distributions of a turbine blade of aspect ratio 0.83 and aspect ratio 3.33 in solid-wall tunnels.

at the exit from the solid-wall cascade was not much greater than that calculated for two-dimensional flow, very little air could be drawn through porous walls without lowering the exit dynamic pressure below the desired value. With this low porous-wall flow rate, the pressure drop across the porous walls in use with this test was not sufficiently great to produce an inflow through the entire wall. Therefore, the flow through the cascade could not be considered valid. Nevertheless, a turning angle only 1° different (in 105°) was measured. This test is at best only indicative of the effects of using porous walls with turbine cascades, but it seems clear that with pressure-drop cascades little benefit is to be gained through the use of permeable side walls.

CONCLUSIONS

The results of an investigation to determine the influence of aspect ratio, boundary-layer control by means of slots and porous surfaces, Reynolds number, and tunnel end-wall condition upon the performance of airfoils in cascades have led to the following conclusions:

1. Conventional cascades of compressor blades with aspect ratio 4 do not simulate the two-dimensional case. The indication is that very large aspect ratios would be necessary to satisfy all criteria of two-dimensionality.

2. Because of opposing effects, the solid-wall cascade of aspect ratio 1 produced a relation between turning angle and angle of attack for the NACA 65-(12)10 compressor blade at a solidity of 1 and an inlet air angle of 60° more nearly like that of two test blowers than that of the solid-wall cascade of aspect ratio 4. However, the normal-force coefficients obtained from the measured pressure distributions were significantly less than those calculated from momentum and pressure changes, and the measured pressure rise across

the cascade was significantly less than that associated with the measured turning angle.

3. With continuous boundary-layer removal, cascades of aspect ratios 1 and 4 produced curves of turning angle against angle of attack for the NACA 65-(12)10 airfoil very similar to those of two test blowers, when the pressure rise associated with the measured turning angle was established.

4. Much better agreement was achieved with the porous-wall cascades between the normal-force coefficients calculated from momentum and pressure changes and those obtained by integration of the measured pressure distributions than was obtained with the solid-wall cascades.

5. With cascades having a decrease in static pressure in the downstream direction, as with guide vanes and turbine blades, the use of permeable walls appears to be of negligible advantage. With such cascades, solid-wall tunnel configurations having blades of aspect ratios of 0.83 and 3.33 produced similar results.

6. For typical compressor-blade cascades in tunnels of low turbulence level, scale effects seem to be negligible above Reynolds numbers of 250,000 but may be appreciable below this value.

7. The porous-wall technique as applied to cascades of compressor blades makes practical the attainment of two-dimensional flows.

REPORT 1017

INVESTIGATION OF FREQUENCY-RESPONSE CHARACTERISTICS OF ENGINE SPEED FOR A TYPICAL TURBINE-PROPELLER ENGINE¹

By BURT L. TAYLOR, III, and FRANK L. OPPENHEIMER

SUMMARY

Experimental frequency-response characteristics of engine speed for a typical turbine-propeller engine are presented. These data were obtained by subjecting the engine to sinusoidal variations of fuel flow and propeller-blade-angle inputs. Correlation is made between these experimental data and analytical frequency-response characteristics obtained from a linear differential equation derived from steady-state torque-speed relations.

The results of this investigation indicate that engine speed is a linear function of fuel flow and propeller-blade angle for limited variations of these parameters. Algebraic expressions approximately describing the frequency-response characteristics of the engine tested are primarily first order. Approximate frequency-response characteristics limited to first-order effects may be calculated from solutions of a linear differential equation and equilibrium torque characteristics of the engine and the propeller.

INTRODUCTION

In order to design controls that will provide desirable transient operation, the dynamics of the various components of the controlled system should be known. The most general description of the dynamics of any system is the differential equations of motion, but use of the detailed and precise aerodynamic and thermodynamic equations for analysis of dynamic behavior of a gas-turbine engine and control system presents insurmountable problems. On the other hand, any description whereby linear behavior of the system components is assumed can be placed in a form that is readily handled and productive of results. The advantages of the linear assumption are so far-reaching that its use is justified, even where the system is of known nonlinearity but where high precision of results is not required, such as in the investigation of controls for gas-turbine engines.

In the linear field, several descriptive forms can be used. The most general of these is the frequency response, whereby the attenuation and the phase lag of steady sinusoidal inputs are given for the continuous frequency spectrum. When these data are available for each component of a closed-loop control system, the time response of the system can be calculated. By employing techniques of analysis and synthesis described in reference 1, system behavior can be altered to obtain desired frequency-response characteristics and the related time response.

A general investigation is in progress at the NACA Lewis laboratory to determine the nature of the dynamics of gas-turbine power plants and to devise and to evaluate methods for describing this behavior in a form applicable to control

synthesis and analysis. Special emphasis has been placed on the determination of the behavior of rotative speed because of its importance in this type of engine for safety and optimum operation. The results of an investigation of the frequency-response characteristics of a turbine-propeller engine are presented herein. Experimental frequency-response data were analyzed to obtain the general form and nature of the frequency-response and dynamic characteristics of such engines, to verify the linear assumption, and to obtain a basis upon which other descriptive forms of the dynamic behavior may be compared. One such comparison is made between the linear differential equation obtained from equilibrium-torque curves and experimental frequency-response characteristics.

For purposes of this investigation, the dynamic response of engine speed to disturbances in fuel flow and propeller-blade angle for a typical turbine-propeller engine is used.

ANALYSIS

DEVELOPMENT OF LINEAR DIFFERENTIAL EQUATIONS

With the hypothesis that quasi-static conditions exist in an engine during transient conditions of operation, a differential equation may be derived to express the behavior of engine speed as a function of fuel flow (reference 2). An assumption is made that the torque output of the engine is some function of only two variables, engine speed and fuel flow, for a given condition of altitude and ram pressure ratio. This function may be expanded and linearized so that the following equation approximates the behavior of engine speed for operation in a small region

$$\left. \begin{aligned} Q_e &= f_1(W_f, N_e) \\ \Delta Q_e &= a \Delta W_f - b \Delta N_e \end{aligned} \right\} \quad (1)$$

where a is the partial derivative of engine torque with respect to fuel flow and b is the absolute value of the partial derivative of engine torque with respect to engine speed. A delta prefix before a variable signifies deviation from the initial operating point. (All symbols used in this report are defined in the appendix.)

In a similar manner, the torque absorbed by a propeller may be expressed as some function of rotational speed and blade angle

$$\left. \begin{aligned} Q_p &= f_2(\beta, N_p) \\ \Delta Q_p &= c \Delta \beta + d \Delta N_p \\ \Delta Q_p &= c \Delta \beta + \frac{d}{R} \Delta N_e \end{aligned} \right\} \quad (2)$$

¹ Supersedes NACA TN 2184, "Investigation of Frequency-Response Characteristics of Engine Speed for a Typical Turbine-Propeller Engine" by Burt L. Taylor, III, and Frank L. Oppenheimer, 1950.

where c is the partial derivative of propeller torque with respect to blade angle and d is the partial derivative of propeller torque with respect to propeller speed.

Any unbalance between torque developed by the engine and torque absorbed by the propeller results in an acceleration. If the effective moment of inertia is assumed to be comprised of the propeller and the rotating parts of the engine, the unbalanced torque may be expressed in terms of engine speed and the moments of inertia by the following equation:

$$\Delta Q_e - \frac{\Delta Q_p}{R} = \left(I_e + \frac{I_p}{R^2} \right) \Delta \dot{N}_e \quad (3)$$

If equation (2) is divided by the gear ratio R and subtracted from equation (1), the following equation results:

$$\left. \begin{aligned} & \frac{\left(I_e + \frac{I_p}{R^2} \right) \Delta N_e}{\left(I_e + \frac{I_p}{R^2} \right) N_{e(max)}} + \left\{ \left[\frac{\partial Q_e}{\partial N_e} \right] \left[\frac{1}{N_{e(max)}} \right] \left(\frac{1}{I_e + \frac{I_p}{R^2}} \right) + \left[\frac{\partial Q_p}{\partial N_p} \right] \left(\frac{1}{R^2} \right) \left[\frac{1}{N_{p(max)}} \right] \left(\frac{1}{I_e + \frac{I_p}{R^2}} \right) \right\} \frac{\Delta N_e}{N_{e(max)}} \\ & = \left[\frac{\partial Q_e}{\partial W_f} \right] \left[\frac{1}{W_{f(max)}} \right] \left[\frac{1}{N_{e(max)}} \right] \left(\frac{1}{I_e + \frac{I_p}{R^2}} \right) \Delta W_f - \left(\frac{\partial Q_p}{\partial \beta} \right) \left(\frac{1}{R} \right) \left[\frac{1}{N_{e(max)}} \right] \left(\frac{1}{I_e + \frac{I_p}{R^2}} \right) \Delta \beta \\ & \quad + \left\{ \frac{\partial \left[\frac{Q_e}{N_{e(max)} I_e \left(1 + \frac{I_p/R^2}{I_e} \right)} \right]}{\partial \left[\frac{N_e}{N_{e(max)}} \right]} + \frac{\partial \left[\frac{Q_p}{N_{p(max)} I_p \left(1 + \frac{I_e}{I_p/R^2} \right)} \right]}{\partial \left[\frac{N_p}{N_{p(max)}} \right]} \right\} \frac{\Delta N_e}{N_{e(max)}} \\ & = \frac{\partial \left[\frac{Q_e}{N_{e(max)} I_e \left(1 + \frac{I_p/R^2}{I_e} \right)} \right]}{\partial \left[\frac{W_f}{W_{f(max)}} \right]} \frac{\Delta W_f}{W_{f(max)}} - \frac{\partial \left[\frac{Q_p}{N_{p(max)} I_p \left(1 + \frac{I_e}{I_p/R^2} \right)} \right]}{\partial \beta} \Delta \beta \\ & \quad \frac{\Delta \dot{N}_e}{N_{e(max)}} + (b_1 + d_1) \frac{\Delta N_e}{N_{e(max)}} = a_1 \frac{\Delta W_f}{W_{f(max)}} - c_1 \Delta \beta \end{aligned} \right\} \quad (6)$$

The form of equation (6) is that of a first-order lag, which can be written as follows:

$$\tau \frac{\Delta \dot{N}_e}{N_{e(max)}} + \frac{\Delta N_e}{N_{e(max)}} = K_1 \frac{\Delta W_f}{W_{f(max)}} - K_2 \Delta \beta \quad (7)$$

where the dynamic characteristics are entirely defined by the time constant τ and the equilibrium condition is defined by K_1 and K_2 . Thus,

$$\left. \begin{aligned} \tau &= \frac{1}{b_1 + d_1} \\ K_1 &= \frac{a_1}{b_1 + d_1} \\ K_2 &= \frac{c_1}{b_1 + d_1} \end{aligned} \right\} \quad (8)$$

$$\Delta Q_e - \frac{\Delta Q_p}{R} = a \Delta W_f - \frac{c}{R} \Delta \beta - \left(b + \frac{d}{R^2} \right) \Delta N_e \quad (4)$$

Equations (3) and (4) may be combined, yielding the following differential equation relating engine speed to fuel flow and blade angle:

$$\left(I_e + \frac{I_p}{R^2} \right) \Delta \dot{N}_e + \left(b + \frac{d}{R^2} \right) \Delta N_e = a \Delta W_f - \frac{c}{R} \Delta \beta \quad (5)$$

If equation (5) is divided through by $N_{e(max)}$ and $\left(I_e + \frac{I_p}{R^2} \right)$ and the appropriate terms are divided by $\frac{N_{e(max)}}{N_{e(max)}}$, $\frac{N_{p(max)}}{N_{p(max)}}$, or $\frac{W_{f(max)}}{W_{f(max)}}$, the following dimensionless equation expressing speed and fuel flow is obtained:

FREQUENCY RESPONSE

Frequency-response characteristics may be calculated by solving the differential equation describing a system subjected to sinusoidal forcing functions of various frequencies. The same results may be obtained by applying the operational calculus to the differential equation. Thus, the response of engine speed to fuel flow at constant blade angle can be expressed in terms of the operator $i\omega$ as follows:

$$\frac{\Delta N_e}{N_{e(max)}} \frac{1}{\Delta W_f} (i\omega) = \frac{K_1}{(1 + i\tau\omega)} \quad (9)$$

which is obtained from equation (7) by replacing the first derivative with respect to time by $(i\omega)$ and treating the

results algebraically. The complex operator represents both the ratio of the amplitudes of the engine-speed and fuel-flow sine waves and the relative phase angles. The amplitude ratio is the absolute value of the complex function, as follows:

$$\left| \frac{\Delta N_e}{N_{e(max)} \frac{\Delta W_f}{W_{f(max)}}} \right| = \frac{K_1}{\sqrt{1 + \tau^2 \omega^2}} \quad (10)$$

The angle by which the engine-speed sine wave lags the fuel-flow sine wave is as follows:

$$\text{Ang} \frac{\Delta N_e}{N_{e(max)} \frac{\Delta W_f}{W_{f(max)}}} = \tan^{-1}(\omega \tau) \quad (11)$$

The frequency response of engine speed to blade angle at constant fuel flow may be obtained by the same procedure,

$$\frac{\Delta N_e}{N_{e(max)} \Delta \beta} (i\omega) = -\frac{K_2}{(1 + i\tau\omega)} \quad (12)$$

$$\left| \frac{\Delta N_e}{N_{e(max)} \Delta \beta} \right| = \frac{K_2}{\sqrt{1 + \tau^2 \omega^2}} \quad (13)$$

$$\text{Ang} \frac{\Delta N_e}{N_{e(max)} \Delta \beta} = \tan^{-1}(\omega \tau) \quad (14)$$

APPARATUS AND PROCEDURE

ENGINE INSTALLATION

Engine.—The principal components of the engine used for the investigation are an axial-flow compressor, reverse-flow combustion chambers, and a single-stage direct-coupled turbine. A two-stage planetary gear system provides a speed reduction between the turbine and the propeller.

A 12-foot-1-inch-diameter, four-bladed propeller was installed on the engine. The pitch-changing mechanism is a self-contained hydraulic unit located in the propeller hub. A lever, or beta arm, on the stationary portion of the hub operates the hydraulic control valves in the rotating part so that a linear relation exists between the beta arm and the blade angle. Each position of the beta arm corresponds to a unique blade angle during steady-state operation.

Harmonic-motion generator.—An approximation of simple harmonic motion by the beta arm was obtained by connecting it to a rotating crank driven by a direct-current motor through a worm gear reduction unit. A minimum ratio of 100:1 between the connecting rod and the crank length made the motion of the beta arm vary less than 1 percent from a true sine wave. By controlling the armature current and

substituting various speed reducers in the harmonic-motion generator, a range of frequencies could be obtained. The center of amplitude of the sine wave could be varied by shifting the position of the harmonic-motion generator, and various amplitudes could be obtained by changing the crank length.

In order to vary fuel flow sinusoidally, the fuel system of the engine was disconnected from the manifold and replaced by an external system, as shown in figure 1. A line was connected in parallel with the main throttle in order to obtain a small variation of fuel input about a center of amplitude set by the main throttle. The harmonic-motion generator used in the blade-angle runs varied the flow in the parallel line by means of a linear valve. Changes in pressure drop across the valve were too small to have an effect upon the linear variation of flow during transient operation.

INSTRUMENTATION

Steady-state measurements were taken of propeller-blade angle, fuel flow, engine torque, and engine speed. Provisions were made to measure all of these variables except the torque during transient conditions of operation.

Blade-angle position was measured by the use of a potentiometer attached to the propeller blade that varied the flow of current in an electric circuit in direct proportion to the blade position. For steady-state measurements, the current was measured by a milliammeter; during transient conditions the circuit was switched to a recording oscillograph element. A conventional slip-ring arrangement was used to complete the circuit between the potentiometer on the propeller hub and the recording device. Beta-arm position was recorded in a similar manner.

In order to measure fuel flow, an A.S.M.E. orifice was installed in the main fuel line immediately upstream of the engine fuel manifold. A bellows-type differential-pressure gage measured the pressure drop across the orifice and actuated a small potentiometer that varied the current in a circuit similar to that used for blade-angle measurement. Inasmuch as flow variations were small in comparison with mean flow, the nonlinear relation between pressure drop and actual flow was insignificant.

FIGURE 1.—System for providing sinusoidal fuel flow.

FIGURE 2.—Schematic diagrams of transient response instrumentation.

The ring gear of the planetary reduction unit of the engine is restrained by a self-balancing hydraulic system. The torque output of the engine was indicated by the pressure required to act on the hydraulic piston to maintain balance. This pressure was measured by a Bourdon gage.

Steady-state measurement of engine speed was accomplished by means of a three-phase tachometer generator and indicator. For recording transients in engine speed on the oscillograph, a direct-current tachometer generator was utilized in a current-measuring circuit.

A 10-cycle-per-second timing signal generated by an audio oscillator was recorded on the oscillograph film to show the time variation of the measured variables. The signal was frequently compared with a standard 60-cycle-per-second current on a cathode-ray oscilloscope for calibration purposes.

Schematic diagrams of the transient measurement circuits are shown in figure 2. Table I indicates the steady-state and transient characteristics of the instruments used. The oscillograph was used to record only increments of deviation from the initial operating point. Conventional steady-state instruments were used to measure the level at which the transient occurred and to evaluate the increments. The oscillograph was calibrated frequently during the runs for known values of deviation as measured by the steady-state instruments.

PROCEDURE

Frequency-response runs.—In order to determine the frequency response of engine speed, sinusoidal variations were made in propeller-blade angle at constant fuel flow and in fuel flow at constant blade angle. The frequency range to be investigated was determined by the following considerations: It is shown in reference 1 that for a first-order system the break frequency is inversely proportional to the system time constant and that an adequate frequency range to describe the unit is 0.1 to 10 times this value. Therefore, by assuming the time constant to be 5 seconds and considering the engine primarily of first order, the range of descriptive frequencies was defined to be 0.02 to 2 radians per second.

Dynamic behavior about two equilibrium running conditions of the engine was investigated. The first condition was 65 percent of maximum rated fuel flow and a blade angle of 18° (97.5 percent of maximum engine speed). The other condition was 81 percent of maximum rated fuel flow and a blade angle of 28° (92.5 percent of maximum engine speed).

The amplitude of the forcing function was the same at each operating condition; namely, a blade angle of 2° and 3.9 percent of maximum rated fuel flow. For each run, oscillographic records were made of the time variation of pertinent variables during steady-state sinusoidal operation. Typical records of these data are reproduced in figure 3. The high frequency variation of the fundamental waves in these figures resulted from electrical and mechanical disturbances to the sensing elements.

- (a) Typical data showing steady-state sinusoidal response of engine speed to blade angle. Fuel flow, 81 percent of maximum rated; mean engine speed, 92.5 percent of maximum; mean blade angle, 28° ; frequency, 0.986 radian per second.
- (b) Typical data showing steady-state sinusoidal response of engine speed to fuel flow. Blade angle, 18° ; mean engine speed, 97.5 percent of maximum; mean fuel flow, 65 percent of maximum rated; frequency, 0.873 radian per second.

FIGURE 3.—Typical steady-state sinusoidal data for turbine-propeller engine.

 (b) Amplitude-ratio relation. Fuel flow, 81 percent of maximum rated; mean engine speed, 92.5 percent of maximum; mean blade angle, 28°; blade-angle amplitude, 2°

(c) Phase-angle relation. Fuel flow, 65 percent of maximum rated; mean engine speed, 97.5 percent of maximum; mean blade angle, 18°; blade-angle amplitude, 2°.
 (d) Phase-angle relation. Fuel flow, 81 percent of maximum rated; mean engine speed, 92.5 percent of maximum; mean blade angle, 28°; blade-angle amplitude, 2°.

FIGURE 4.—Propeller-blade angle—engine-speed relations at constant fuel flow obtained from experimental sinusoidal response data for typical turbine-propeller engine.

Equilibrium runs.—Equilibrium data required to evaluate the constants of equation (6) were obtained by the following procedure: For a set value of fuel flow, propeller-blade angle was adjusted to obtain nine operating points between 85 and 100 percent of maximum engine speed. These speed points were used for fuel flows of 50.0, 57.6, 65.4, 69.1, 77.0, and 84.5 percent of maximum fuel flow except when torque or turbine-outlet-temperature limitations prohibited operation throughout the complete range. Engine torque, engine speed, fuel flow, and blade-angle measurements were taken at each operating point.

RESULTS AND DISCUSSION

EXPERIMENTALLY DETERMINED FREQUENCY-RESPONSE CHARACTERISTICS

Results of sinusoidal inputs.—Results of the sinusoidal blade-angle and fuel-flow inputs as obtained from the oscillographic traces are shown in figures 4 and 5. Amplitude ratio of output to input is presented on log-log coordinates as a function of frequency. Phase-angle lag of the output relative to input is presented on semilog coordinates as a function of frequency.

The form of these frequency-response curves indicates the nature of the dynamic characteristics of this power plant.

(a) Amplitude-ratio relation. Mean fuel flow, 65 percent of maximum rated; mean engine speed, 97.5 percent of maximum; blade angle, 18°; fuel-flow amplitude, 3.9 percent of maximum.
 (b) Amplitude-ratio relation. Mean fuel flow, 81 percent of maximum rated; mean engine speed, 92.5 percent of maximum; blade angle, 28°; fuel-flow amplitude, 3.9 percent of maximum.

FIGURE 5.—Fuel-flow—engine-speed relations at constant blade angle obtained from experimental sinusoidal response data for typical turbine-propeller engine.

The regularity of data points indicates that the system follows these predicted characteristics better than might be anticipated. Furthermore, in support of the assumptions made for the differential-equation analysis, the system appears to be primarily a first-order lag system. Despite the complexity of the physical system and the processes performed in the turbine cycle, a fairly simple mathematical form approximates the actual behavior of the engine.

Algebraic form of data.—As shown in figures 4 and 5, although the system is primarily first order, higher order effects are present. Increased attenuation of the output amplitude at phase shifts approaching 180° indicates that a second-order approximation may more exactly describe the data. An equation of the following form has therefore been fitted to the experimental data:

$$\frac{\text{output}}{\text{input}} = \frac{K}{(1 + i\tau_1\omega)(1 + i\tau_2\omega)}$$

The equation was matched to the experimental data at the steady-state point and at phase shifts of 45° and 90°, thereby determining the three variables of the equation, K , τ_1 , and τ_2 . Results of these computations are presented in column 3 of table II.

(c) Phase-angle relation. Mean fuel flow, 65 percent of maximum rated; mean engine speed, 97.5 percent of maximum; blade angle, 18°; fuel-flow amplitude, 3.9 percent of maximum.
 (d) Phase-angle relation. Mean fuel flow, 81 percent of maximum rated; mean engine speed, 92.5 percent of maximum; blade angle, 28°; fuel-flow amplitude, 3.9 percent of maximum.

FIGURE 5.—Concluded. Fuel-flow—engine-speed relations at constant blade angle obtained from experimental sinusoidal response data for typical turbine-propeller engine.

A maximum error in the value of the second time constant τ_2 of 0.1 second could be attributed to instrument lags; the numerical values for this time constant τ_2 are therefore presented only to indicate the order of magnitude of this second-order effect. Because the fuel-measurement device was slower than the blade-angle measurement circuit, instrumentation error would reduce the value of τ_2 in the functions of engine speed to fuel flow input. The opposite trend of experimental results indicates that the second-order effect is an engine phenomenon. The fact that a ratio in the order of 10:1 exists between the two time constants τ_1 and τ_2 makes the second-order effect negligible for many problems of control analysis.

In order to compare the form of the algebraic approximations with the actual data, cross plots of figures 4 and 5 are presented on figures 6 and 7, respectively, together with curves of the algebraic expressions. The calculated first-order curves of figures 6 and 7 will be subsequently discussed.

FIGURE 7.—Frequency response of engine speed to variations in fuel flow obtained from experimental data and theoretical calculations for typical turbine-propeller engine.

Comparison of frequency-response functions.—Variation of the first-order time constant with operating conditions may be of more importance than the second-order effect. A comparison of first-order time constants in table II shows that these constants not only vary with the engine-power points but also vary with the forcing function at the same power point. For an exact description of dynamic behavior of engine speed, extensive data may be required to determine the trend of transient characteristics.

Linearity of dynamic behavior.—For purposes of analysis, an assumption was made that engine speed was a linear function of fuel flow and blade angle for small transients. In

order to evaluate this assumption from the results of experimental data, the form of the outputs recorded on oscillograph film was compared with an analytical sine wave. For inputs resulting in engine-speed changes of as much as 6 percent of maximum speed the form of the speed sine wave varied negligibly from an exact sine wave. Greater input amplitudes resulting in larger speed oscillations caused appreciable distortion, the effect being greater at low-power points. An assumption of linearity is therefore justified only for restricted deviations on the order of 3 or 4 percent from an equilibrium point.

FIGURE 8.—Relation between engine-torque parameter, percentage of maximum engine speed, and percentage of maximum rated fuel flow as obtained from experimental data for typical turbine-propeller engine.

ANALYTICALLY DETERMINED FREQUENCY-RESPONSE CHARACTERISTICS

Results of equilibrium runs.—The relation between steady-state values of engine torque and fuel flow is plotted in figure 8 (a) for several values of constant speed. Cross plots for lines of constant fuel flow are shown in figure 8 (b). Figure 9 (a) is a plot of propeller torque against blade angle for various values of constant speed and cross plots for lines of constant blade angle are shown in figure 9 (b). In order to show the equilibrium running conditions about which sinusoidal data were taken, two lines of constant blade angle, 18° and 28°, are superimposed on figure 8 (b).

Losses to the accessories and the gear reduction unit were neglected in calculations of propeller torque.

Range of linearity.—In the derivation of equations (1) and (2), an assumption was made that the relations presented in figures 8 and 9 may be considered as straight lines for small deviations from a given steady-state point. The actual data indicate that this assumption is justified for the engine characteristics over rather large regions, but the propeller characteristics should be considered linear only in very small regions. Furthermore, these engine data as obtained under steady-state conditions of operation may not be accurate under transient conditions if the turbine is required to operate at a point far from the design condition (reference 2).

Analytical sinusoidal response.—Frequency-response characteristics of the engine were calculated for operating points at which experimental sinusoidal data were taken. Values of the constants a_1 , b_1 , c_1 , and d_1 for an operating condition were obtained from the slopes of the curves of figures 8 (a), 8 (b), 9 (a), and 9 (b), respectively. With values so determined, equations (10), (11), (13), and (14) were evaluated

for a range of frequencies coinciding with that used in the experimental runs. Results of these calculations are included in figures 6 and 7.

Algebraic form of analytical results.—The algebraic form of the first-order curves presented in figures 6 and 7 is shown in equations (9) and (12). These equations were evaluated for the selected operating points and the results are presented in column 4 of table II.

For the assumptions made in the analysis, the engine time constant is independent of the forcing function, as shown in equation (7). Variation of time constants for the two power points results from the nonlinearity of torque-speed characteristics of the engine and the propeller. The magnitude of this variation is sufficient to limit the utility of an analysis in which linear approximations are assumed. For studies of behavior within restricted regions, the analysis is satisfactory.

COMPARISON OF DIFFERENTIAL-EQUATION SOLUTION WITH EXPERIMENTAL RESULTS

Comparison of form.—Calculated frequency-response characteristics are similar to the experimental results at low-frequency values, as shown by figures 6 and 7. Because of higher-order effects exhibited by the experimental data, deviation between the two sets of curves increases at higher frequencies. This effect is particularly evident in the phase shift occurring at high frequencies. Presence of phase shifts greater than 90° in the engine system may limit the over-all loop gain for stability in a combined engine and control system. For the usual case in which the control contributes at least 90° additional phase shift to the engine polar diagram, the gain at the 180° phase shift point has a definite limit according to the Nyquist criterion (reference 1).

FIGURE 9.—Relations between propeller-torque parameter, percentage of maximum propeller speed, and blade angle for 12-foot-1-inch-diameter, four-bladed propeller.

(b) Constant blade-angle characteristics. (Cross-plotted from fig. 9(a).)

FIGURE 9.—Concluded. Relations between propeller-torque parameter, percentage of maximum propeller speed, and blade angle for 12-foot-1-inch-diameter, four-bladed propeller.

Comparison of numerical values.—In general, the value of the experimental time constant is lower than the value of the analytical time constant for a given power operating point. The significance of this variation depends on the particular application of the data; for some problems of control analysis

a range of variation of 2 to 1 in the engine time constant causes little change in the combined engine-control system. Discrepancies between steady-state gain values, analytical and experimental, can be accounted for by the fact that the analytical values are calculated from slopes of equilibrium-torque curves.

CONCLUSIONS

From a sea-level static investigation of the frequency-response characteristics of a turbine-propeller engine, the following conclusions may be drawn:

1. Engine speed is a linear function of fuel flow and propeller-blade angle during transient operation, if deviations from the equilibrium operating point are of the order of 3 or 4 percent.

2. The frequency-response functions of engine speed to fuel flow and engine speed to blade angle are primarily first order, but higher-order effects exist.

3. A differential equation that closely describes engine speed as a function of fuel flow and blade angle can be derived from steady-state data.

REPORT 1018

A THEORETICAL ANALYSIS OF THE EFFECT OF TIME LAG IN AN AUTOMATIC STABILIZATION SYSTEM ON THE LATERAL OSCILLATORY STABILITY OF AN AIRPLANE¹

By LEONARD STERNFIELD and ORDWAY B. GATES, Jr.

SUMMARY

A method is presented for determining the effect of time lag in an automatic stabilization system on the lateral oscillatory stability of an airplane. The method is based on an analytical-graphical procedure. The critical time lag of the airplane-autopilot system is readily determined from the frequency-response analysis.

The method is applied to a typical present-day airplane equipped with an automatic pilot sensitive to yawing acceleration and geared to the rudder so that rudder control is applied in proportion to the yawing acceleration. The results calculated for this airplane-autopilot system by this method are compared with the airplane motions calculated by a step-by-step procedure.

INTRODUCTION

Recent calculations and flight tests of several airplanes designed for operation in the transonic speed range have indicated unsatisfactory damping of the lateral oscillation. The results presented in reference 1 show that the oscillatory stability can be improved by the use of an automatic pilot. The calculations of reference 1, however, were made on the assumption of an idealized control system without lag. Reference 2 points out that lag of the type in which the amount of control applied at a given instant is assumed to be proportional to a deviation which existed at a fixed time previous to the given instant can be represented mathematically by use of the lag operator $e^{-\tau_s D_b}$, where τ_s is nondimensional time lag based on the span and D_b is the differential operator. Lag of this type is generally referred to as time lag. Reference 2 suggests that for purposes of calculation the lag operator may be approximated by three terms of the Taylor's series for $e^{-\tau_s D_b}$. This approximation was used in some recent calculations (reference 3) and the results were found to be erroneous and misleading. The purpose of this report is to present a satisfactory method for determining the effect of time lag on the lateral oscillatory stability based on the exact expression of the lag operator rather than any approximation. Some recent analyses on the same problem, unknown to the authors at the time this problem was being analyzed, are presented in references 4 and 5.

SYMBOLS AND COEFFICIENTS

ϕ	angle of roll, radians
ψ	angle of yaw, radians
β	angle of sideslip, radians (v/V)
r	yawing angular velocity, radians per second ($d\psi/dt$)
$\ddot{\psi}$	yawing angular acceleration, radians per second per second ($d^2\psi/dt^2$)
p	rolling angular velocity, radians per second ($d\phi/dt$)
v	sideslip velocity along lateral axis, feet per second
V	airspeed, feet per second
ρ	mass density of air, slugs per cubic foot
q	dynamic pressure, pounds per square foot ($\frac{1}{2} \rho V^2$)
b	wing span, feet
S	wing area, square feet
W	weight of airplane, pounds
m	mass of airplane, slugs (W/g)
g	acceleration due to gravity, feet per second per second
μ_b	relative-density factor ($m/\rho Sb$)
η	inclination of principal longitudinal axis of airplane with respect to flight path, positive when principal axis is above flight path at nose, degrees
γ	angle of flight path to horizontal axis, positive in a climb, degrees
k_{x_0}	radius of gyration in roll about principal longitudinal axis, feet
k_{z_0}	radius of gyration in yaw about principal vertical axis, feet
K_{x_0}	nondimensional radius of gyration in roll about principal longitudinal axis (k_{x_0}/b)
K_{z_0}	nondimensional radius of gyration in yaw about principal vertical axis (k_{z_0}/b)
K_x	nondimensional radius of gyration in roll about longitudinal stability axis ($\sqrt{K_{x_0}^2 \cos^2 \eta + K_{z_0}^2 \sin^2 \eta}$)

¹ Supersedes NACA TN 2005, "A Theoretical Analysis of the Effect of Time Lag in an Automatic Stabilization System on the Lateral Oscillatory Stability of an Airplane" by Leonard Sternfield and Ordway B. Gates, Jr., 1950.

K_z	nondimensional radius of gyration in yaw about vertical stability axis $(\sqrt{K_{z_0}^2 \cos^2 \eta + K_{x_0}^2 \sin^2 \eta})$
K_{xz}	nondimensional product-of-inertia parameter $((K_{z_0}^2 - K_{x_0}^2) \sin \eta \cos \eta)$
C_L	trim lift coefficient $(\frac{W \cos \gamma}{qS})$
C_l	rolling-moment coefficient $(\frac{\text{Rolling moment}}{qSb})$
C_N	yawing-moment coefficient $(\frac{\text{Yawing moment}}{qSb})$
C_Y	lateral-force coefficient $(\frac{\text{Lateral force}}{qS})$
$C_{l_\beta} = \frac{\partial C_l}{\partial \beta}$	
$C_{n_\beta} = \frac{\partial C_n}{\partial \beta}$	
$C_{Y_\beta} = \frac{\partial C_Y}{\partial \beta}$	
$C_{n_r} = \frac{\partial C_n}{\partial \frac{rb}{2V}}$	
$C_{n_p} = \frac{\partial C_n}{\partial \frac{pb}{2V}}$	
$C_{l_p} = \frac{\partial C_l}{\partial \frac{pb}{2V}}$	
$C_{Y_p} = \frac{\partial C_Y}{\partial \frac{pb}{2V}}$	
$C_{Y_r} = \frac{\partial C_Y}{\partial \frac{rb}{2V}}$	
$C_{l_r} = \frac{\partial C_l}{\partial \frac{rb}{2V}}$	
$C_{n_{\delta_r}} = \frac{\partial C_n}{\partial \delta_r}$	
t	time, seconds
s_b	nondimensional time parameter based on span (Vt/b)
D_b	differential operator $(\frac{d}{ds_b})$
P	period of oscillation, seconds
$T_{1/2}$	time for amplitude of oscillation to damp to one-half its original value
δ_r	deflection of control, radians
a	real part of complex root of characteristic stability equation
ω	angular frequency, radians per second
$\omega_s = \frac{b}{V} \omega$	
$\lambda = a + i\omega_s$	
τ	time lag between signal for control and its actual motion, seconds
$\tau_s = \frac{V}{b} \tau$	

$(\tau)_c$	critical time lag
K_A	maximum amplitude of acceleration in yaw produced by control deflection of unit amplitude $(\left \frac{\ddot{\psi}}{\delta_r} \right _{\text{airplane}})$
$(K_A)_s = \frac{b^2}{V^2} K_A$	
k	amplitude of control-surface oscillation produced by autopilot in response to oscillation of airplane acceleration $(\left \frac{\delta_r}{\ddot{\psi}} \right _{\text{autopilot}})$
$k_s = \frac{V^2}{b^2} k$	
$K_c = \frac{1}{k}$	
$(K_c)_s = \frac{1}{k_s}$	
θ	phase angle, radians
θ_A	phase angle of lag of δ_r behind $\ddot{\psi}$ when oscillating control surface forces airplane to oscillate, radians
θ_C	phase angle obtained from frequency response of autopilot

ANALYSIS

The investigation of the effect of time lag on the lateral oscillation may be conveniently divided into two parts: (a) determination of the smallest time lag which would result in a neutrally stable oscillation, referred to as critical time lag, and (b) the effect of a given time lag on the lateral oscillatory stability. It is important to know some of the results of the analysis obtained in part (a) in order to facilitate the analysis presented in part (b). Part (a) is based on the frequency-response method of analysis (references 6 and 7). This method affords a relatively simple means of determining the critical time lag of an automatic stabilization system and thereby of establishing the range of time lags for which the airplane motion is stable. Part (b) treats the solution of a transcendental equation by means of an analytical-graphical procedure. The analysis is presented for an airplane equipped with an automatic pilot sensitive to yawing acceleration and geared to the rudder so that rudder control is applied in proportion to the yawing acceleration, as suggested in reference 3. A similar analysis is applicable, however, to any automatic stabilization system with time lag.

The equations of motion used are expressed in terms of the nondimensional time parameter based on the span of the airplane $s_b = \frac{Vt}{b}$, but the results of the calculations obtained in terms of s_b have been converted from the nondimensional time s_b to time t in seconds. Thus the discussion of the results and the figures included in the report are given in terms of t .

DETERMINATION OF CRITICAL TIME LAG

The critical time lag of a system is defined as the time lag that results in a neutrally stable or steady-state oscillation. The motion of the control δ_r and the airplane acceleration $\ddot{\psi}$ when a critical time lag exists are shown in figure 1. This

FIGURE 1.—The relationship between the airplane acceleration and the control motion for the case of critical time lag. $\theta = \omega \Delta t$; $\Delta t = \tau = \frac{\theta}{\omega}$.

figure indicates that the relationship between the time lag τ and the phase angle θ between the motion of the control and the airplane acceleration can be expressed as $\tau = \frac{\theta}{\omega}$. Since τ can be expressed as a function of θ , the frequency-response

method can be utilized to determine the critical time lag for a combined airplane-autopilot system. This method requires that the frequency-response curves be calculated for the airplane and autopilot separately and the results analyzed to ascertain the conditions for neutral oscillatory stability of the airplane-autopilot system.

Frequency-response curves for airplane.—The frequency-response curves for the airplane are obtained from the calculation of the steady-state motion of the airplane in response to a sinusoidal forcing function of unit amplitude (see reference 8). Thus if

$$\delta_r = \sin \omega_s s_b$$

the acceleration of the airplane is

$$D_b^2 \psi = (K_A)_s \sin (\omega_s s_b + \theta_A)$$

The values of $(K_A)_s$, known as the amplitude ratio, and θ_A are obtained over the desired range of angular frequencies by substituting $i\omega_s$ for D_b in the expression for $D_b^2 \psi / \delta_r$ which is derived from the lateral equations of motion. The non-dimensional lateral equations of motion, referred to stability axes, for a given control deflection are

$$\left. \begin{aligned} \left(2\mu_b K_X^2 D_b^2 - \frac{1}{2} C_{l_p} D_b \right) \phi + \left(2\mu_b K_{XZ} D_b^2 - \frac{1}{2} C_{l_r} D_b \right) \psi - C_{l_\beta} \beta &= 0 \\ \left(2\mu_b K_{XZ} D_b^2 - \frac{1}{2} C_{n_p} D_b \right) \phi + \left(2\mu_b K_Z^2 D_b^2 - \frac{1}{2} C_{n_r} D_b \right) \psi - C_{n_\beta} \beta &= C_{n_{\delta_r}} \delta_r \\ \left(-\frac{1}{2} C_{Y_p} D_b - C_L \right) \phi + \left(2\mu_b D_b - \frac{1}{2} C_{Y_r} D_b - C_L \tan \gamma \right) \psi + (2\mu_b D_b - C_{Y_\beta}) \beta &= 0 \end{aligned} \right\} \quad (1)$$

The derivatives $C_{l_{\delta_r}} = \frac{\partial C_l}{\partial \delta_r}$ and $C_{Y_{\delta_r}} = \frac{\partial C_Y}{\partial \delta_r}$ are usually very small and therefore have been neglected in equations (1).

Hence,

$$\frac{D_b^2 \psi}{\delta_r} = \frac{\begin{vmatrix} 2\mu_b K_X^2 D_b^2 - \frac{1}{2} C_{l_p} D_b & 0 & -C_{l_\beta} \\ 2\mu_b K_{XZ} D_b^2 - \frac{1}{2} C_{n_p} D_b & C_{n_{\delta_r}} & -C_{n_\beta} \\ -\frac{1}{2} C_{Y_p} D_b - C_L & 0 & 2\mu_b D_b - C_{Y_\beta} \end{vmatrix}}{\begin{vmatrix} 2\mu_b K_X^2 D_b^2 - \frac{1}{2} C_{l_p} D_b & 2\mu_b K_{XZ} D_b^2 - \frac{1}{2} C_{l_r} D_b & -C_{l_\beta} \\ 2\mu_b K_{XZ} D_b^2 - \frac{1}{2} C_{n_p} D_b & 2\mu_b K_Z^2 D_b^2 - \frac{1}{2} C_{n_r} D_b & -C_{n_\beta} \\ -\frac{1}{2} C_{Y_p} D_b - C_L & \left(2\mu_b - \frac{1}{2} C_{Y_r} \right) D_b - C_L \tan \gamma & 2\mu_b D_b - C_{Y_\beta} \end{vmatrix}} \quad (2)$$

After the numerator and denominator are expanded by the method of determinants, the expression for $D_b^2 \psi / \delta_r$ results in the ratio of two polynomials in D_b . The substitution of $i\omega_s$ for D_b in equation (2) gives a complex number $A + iB$ which may be expressed as $(K_A)_s e^{i\theta_A}$. The amplitude ratio

$(K_A)_s$, which is equal to $K_A \frac{b^2}{V^2}$, can be determined from the relation $(K_A)_s = \sqrt{A^2 + B^2}$. The phase angle θ_A can be determined from the relation $\theta_A = \tan^{-1} \frac{B}{A}$.

Frequency response of autopilot.—The frequency response of the autopilot is obtained from the equation for the control motion with time lag taken into account

$$\delta_r = k_s D_b^2 \psi(s_b - \tau_s) \quad (3a)$$

where the term $D_b^2 \psi(s_b - \tau_s)$ signifies the fact that the amount of control applied at a given instant is proportional to the acceleration at a fixed time τ_s previous to the given instant. This time-lag effect can be expressed by the so-called lag operator $e^{-\tau_s D_b}$. Thus equation (3a) becomes

$$\delta_r = k_s D_b^2 \psi e^{-\tau_s D_b} \quad (3b)$$

Solving equation (3b) for $D_b^2 \psi / \delta_r$ gives

$$\frac{D_b^2 \psi}{\delta_r} = \frac{1}{k_s} e^{\tau_s D_b} = (K_C)_s e^{\tau_s D_b} \quad (4)$$

where

$$(K_C)_s = \frac{b^2}{V^2} K_C = \frac{b^2}{V^2} \left| \frac{\ddot{\psi}}{\delta_r} \right|_{\text{autopilot}}$$

Substituting $i\omega_s$ for D_b in equation (4) results in an amplitude ratio $(K_C)_s = \frac{1}{k_s}$, which is independent of frequency, and a phase angle $\theta_C = \tau_s \omega_s$.

Conditions for stability.—The necessary and sufficient conditions for any one of the oscillatory modes to be neutrally stable are that, at a particular frequency, the phase angles and amplitude ratios of the airplane and autopilot must be equal—that is, $\theta_A = \theta_C$ and $(K_A)_s = (K_C)_s$. Even though these conditions are satisfied, the resultant motion of the airplane which is composed of all the individual modes of motion may be unstable since, as is pointed out subsequently, an additional unstable oscillatory mode may be present. In general, the condition which must be satisfied in order that all the oscillatory modes be stable is that, at each angular frequency where $\theta_A = \theta_C$, the ratio $\frac{(K_A)_s}{(K_C)_s}$ must be less than 1 at that frequency. The mathematical proof of this statement is given in reference 9.

Illustrative example.—The foregoing method is applied to a typical present-day high-speed airplane having the characteristics presented in table I. The value of the control-gearing ratio k is arbitrarily assumed to be 0.0427. (This value of $k=0.0427$ corresponds to a rudder deflection of 1° for a yawing acceleration of $23.4^\circ/\text{sec}/\text{sec}$.) The amplitude-ratio and phase-angle curves for the airplane, plotted as a function of angular frequency ω , where $\omega = \omega_s \frac{V}{b}$, are presented as solid-line curves in figures 2 (a) and 2 (b), respectively. As the frequency increases to infinity, K_A approaches a value of 15.98 and θ_A approaches π . The dashed line in figure 2 (a), which is independent of frequency, is the amplitude ratio of the autopilot K_C . The phase-angle curves of the autopilot are straight lines with slopes equal to τ , where

$\tau = \frac{b}{V} \tau_s$, and are shown as dashed lines in figure 2 (b) for several values of τ . Since the phase angle remains between the range of 0 to 2π , $\theta_C = \tau\omega$ continues to repeat itself whenever $\tau\omega \geq 2\pi$. To take account of this fact, θ_C is plotted as a series of parallel lines for each value of τ . Figure 2 (a) indicates that $K_A = K_C$ at $\omega=3.8$ and $\omega=8.5$. The corresponding values of τ where $\theta_A = \theta_C$ at $\omega=3.8$ and $\omega=8.5$ are $\tau=1.63$ and $\tau=0.38$, respectively. One of the oscillatory modes of motion is thus neutrally stable when $\tau=1.63$ and $\tau=0.38$. However, as mentioned previously, the motion of the airplane is neutrally stable only if all other oscillatory modes present are stable. This condition is satisfied for $\tau=0.38$, since for each value of ω where $\theta_A = \theta_C$ the ratio $\frac{K_A}{K_C} < 1$. When $\tau=1.63$, one of the oscillatory modes is neutrally stable but the system is unstable, because at $\omega=6$, $\theta_A = \theta_C$ but $\frac{K_A}{K_C} > 1$. An analysis indicates that for values

of $K_C < 15.98$, which is the limiting value of K_A , the system will be unstable for any infinitesimal time lag. The reason for the instability is that, for any infinitesimal time lag, the value of θ_A is equal to θ_C at some high frequency where it can be shown that $\frac{K_A}{K_C} > 1$ since at the very high frequencies

$$\frac{K_A}{K_C} = \frac{(K_A)_{\omega \rightarrow \infty} + \Delta K_A}{(K_A)_{\omega \rightarrow \infty} - \Delta K_C}$$

where ΔK_A and ΔK_C are small incremental values.

FIGURE 2.—Frequency-response curves of the typical present-day airplane and the assumed autopilot.

In order to verify the results predicted by the preceding analysis, motions of the airplane were calculated subsequent to an initial disturbance of 5° in sideslip. The calculations involved a step-by-step procedure based on the Kutta 3/8 method (reference 10). The results of these calculations for $\tau=0.38$ and $\tau=1.63$ are presented in figures 3 and 4, respectively. The solid-line curve in figure 3 was obtained by using a time increment of 0.095 and the motion is seen to be slightly unstable, whereas neutral stability is predicted by frequency-response analysis for $\tau=0.38$. An additional calculation was made by using a time increment of 0.0475, represented by the dashed-line curve in figure 3, and although the motion was still slightly unstable, the trend indicated by reducing the time increment was such as to make the oscillation more nearly neutrally stable. The airplane motion for $\tau=1.63$ is presented in figure 4 and, as was predicted, the motion is unstable. A neutrally stable oscillation was also predicted for this value of time lag but it is apparent

from figure 4 that the unstable mode influences the airplane motion more than the neutrally stable mode.

EFFECT OF TIME LAG ON LATERAL OSCILLATORY STABILITY

Derivation of equations.—The nondimensional equations of motion, referred to the stability axes, which include the effect of an autopilot applying rudder control in proportion to the yawing acceleration at time $s_b - \tau_s$, are obtained by combining equation (3b) with equations (1). When $\phi_0 e^{\lambda s_b}$ is substituted for ϕ , $\psi_0 e^{\lambda s_b}$ for ψ , and $\beta_0 e^{\lambda s_b}$ for β in the resultant equation written in determinant form, λ must be a root of the characteristic stability equation

$$A\lambda^4 + B\lambda^3 + C\lambda^2 + D\lambda + E + k_s e^{-\tau_s \lambda} (A'\lambda^4 + B'\lambda^3 + C'\lambda^2 + D'\lambda) = 0 \quad (5)$$

where $A, B, C, D, E, A', B', C',$ and D' are functions of the mass and aerodynamic parameters of the airplane. The

FIGURE 3.—Effect of $\tau=0.38$ on the motion of the airplane.

expressions for A , B , C , D , and E are given in reference 1 and

$$A' = -4\mu_b^2 K_x^2 C_{n_s},$$

$$B' = (2\mu_b K_x^2 C_{Y_\beta} + \mu_b C_{i_p}) C_{n_s},$$

$$C' = \left(-\frac{1}{2} C_{i_p} C_{Y_\beta} + \frac{1}{2} C_{Y_p} C_{i_\beta} \right) C_{n_s},$$

$$D' = C_L C_{i_\beta} C_{n_s},$$

The damping and period of the lateral oscillation in seconds are given by the expressions

$$\left. \begin{aligned} T_{\frac{1}{2}} &= \frac{-0.693}{a} \frac{b}{V} \\ P &= \frac{2\pi}{\omega_s} \frac{b}{V} \end{aligned} \right\} \quad (6)$$

where a and ω_s are the real and imaginary parts of a complex root of equation (5).

Determination of roots of transcendental equation.—The characteristic stability equation of this system (equation (5)) is seen to be a transcendental equation because a constant time lag τ_s in the automatic stabilization system is represented by the so-called lag operator $e^{-\tau_s D}$. It is apparent that the complex roots of such an equation cannot be determined by conventional methods. A method of obtaining the complex roots of this transcendental equation for a particular value of τ_s is therefore presented.

If $a + i\omega_s$ is substituted for λ in equation (5) and the real and imaginary quantities are separated, two equations in a and ω_s result:

$$e^{-\tau_s a} = F_1(a, \omega_s) \quad (7a)$$

$$e^{-\tau_s \omega_s} = F_2(a, \omega_s) \quad (7b)$$

FIGURE 4.—Effect of $\tau = 1.63$ on the motion of the airplane.

A simultaneous solution of equations (7a) and (7b) gives the desired values of a and ω_s which satisfy equation (5). The method used to solve equations (7a) and (7b) simultaneously is basically a graphical procedure. For a series of values of ω_s , the right-hand sides of equations (7a) and (7b) are plotted against a as illustrated in figure 5. The solid lines and dashed lines correspond to the functions $F_1(a, \omega_s)$ and $F_2(a, \omega_s)$, respectively. The variation of $e^{-\tau_s a}$ with a is also plotted in figure 5. The exact values of a and ω_s for which $F_1(a, \omega_s) = F_2(a, \omega_s) = e^{-\tau_s a}$ are determined from a cross plot of the results of figure 5 as shown in figure 6. In this figure, with a as the abscissa and ω_s as the ordinate, are plotted the values of a and ω_s which correspond to the intersection of the $e^{-\tau_s a}$ curve with the functions $F_1(a, \omega_s)$ and $F_2(a, \omega_s)$. The solid curve in figure 6 thus satisfies the equation $e^{-\tau_s a} = F_1(a, \omega_s)$ and the dashed curve satisfies the equation $e^{-\tau_s a} = F_2(a, \omega_s)$. The values of a and ω_s at the intersection of these two curves therefore determine a root of the characteristic stability equation (equation (5)). The period and damping of the lateral oscillation are determined from equations (6) by using this root.

FIGURE 5.—The effect of a and ω_s on the functions $F_1(a, \omega_s)$, $F_2(a, \omega_s)$, and $e^{-\tau_s a}$.

FIGURE 6.—A cross plot of the points of intersection of $F_1(a, \omega_s)$ and $F_2(a, \omega_s)$ with $e^{-\tau_s a}$ as determined from figure 5.

An alternative method for the simultaneous solution of equations (7a) and (7b) is to substitute $1 - \tau_s a + \frac{\tau_s^2 a^2}{2} - \frac{\tau_s^3 a^3}{6}$ for $e^{-\tau_s a}$ in each of these equations. The calculations involved become considerably less laborious when this approximation is made and results obtained by using this alternative method have been found to be in excellent agreement with results obtained from the method described previously. Figure 7 shows that for $|\tau_s a| = 1$ very close agreement is obtained between the exact value of $e^{-\tau_s a}$ and its approximation by three and four terms of the series for $e^{-\tau_s a}$. In actual practice the product $\tau_s a$ will almost invariably be much less than 1. When this substitution is made, both equations (7a) and (7b) become seventh degree in a for a given value of ω_s . Although these equations are of high degree, no serious problem is presented since the values of a desired must be real and, in general, small; that is, only one or two of the roots of these high-degree equations are of interest. In order to calculate the complex roots of equation (5) for a particular value of τ_s , the following procedure should be used. For a sequence of values of ω_s , compute a from equations (7a) and (7b). The results obtained from each equation may then be plotted in a figure similar to figure 6 and the complex root of the characteristic stability equation determined from the intersection of the two resulting curves. If the value of the approximate series for $e^{-\tau_s a}$ is in good agreement with the exact value of $e^{-\tau_s a}$ for the a determined from the intersection of the two curves, then the complex root obtained is valid. A point of intersection for a value of a which would not give satisfactory agreement between the approximate series and $e^{-\tau_s a}$ might exist, however. If such be the case, the accurate point of intersection is readily ascertained. The estimated values of a and ω_s represent the point of intersection of $F_1(a, \omega_s)$ or $F_2(a, \omega_s)$ with the series approximating $e^{-\tau_s a}$. The desired point is the point of intersection of $F_1(a, \omega_s)$ or $F_2(a, \omega_s)$ with $e^{-\tau_s a}$. The first step is to evaluate the term $e^{-\tau_s a}$ for several values of a in the vicinity of the estimated point of intersection. The expressions $F_1(a, \omega_s)$ and $F_2(a, \omega_s)$ are then evaluated for values of ω_s slightly less than and greater than the estimated value of ω_s for several values of a in the range of the estimated point of intersection. Thus, the corrected curves of equations (7a) and (7b) are obtained and at their point of intersection, the accurate values of a and ω_s are determined.

A method for constructing curves of constant period and damping as a function of τ_s and k_s is presented in the appendix.

Range of ω_s and a to be used in the determination of the complex roots of the characteristic stability equation.—In

FIGURE 7.—A comparison between $e^{-\tau_s a}$ and its approximation by three and four terms of the series for $e^{-\tau_s a}$.

general, the analysis required to determine the damping of the airplane-autopilot system would be carried out for those values of τ_s that result in a stable system, since the purpose of equipping an airplane with an autopilot is to stabilize or increase the damping of the airplane motions. The range of τ_s for which the system is stable is determined from the frequency-response curves of the airplane and autopilot as indicated in the section entitled "Determination of Critical Time Lag." Thus, if the system is stable, only negative values of a need be investigated. Also, if two stable oscillatory modes of motion exist, the least stable one is of greatest interest—that is, the complex root with the smallest real part is the one of most importance.

The estimated range of values for ω_s that should be used

in the analysis to determine the effect of some particular value of time lag, located between $\tau_s=0$ and the critical time lag $(\tau_s)_c$, on the damping of the oscillation is obtained from the known values of the frequency of the oscillation for the cases where $\tau_s=0$ and $\tau_s=(\tau_s)_c$. The imaginary part of the complex root of equation (5), which becomes a quartic equation when $\tau_s=0$, gives the value of ω_s for the case of $\tau_s=0$. The value of ω_s for $\tau_s=(\tau_s)_c$ is determined from the analysis presented in the section entitled "Determination of Critical Time Lag." As mentioned in reference 11, the frequency of the oscillation decreases as time lag increases; thus for a value of $0 < \tau_s < (\tau_s)_c$, the estimated values of ω_s should include frequencies greater than the value of ω_s at $\tau_s=(\tau_s)_c$ and less than the value of ω_s at $\tau_s=0$.

FIGURE 8.—Effect of time lag on the airplane motion in sideslip.

Airplane motions for various values of τ .—For purposes of comparison, the motion of the airplane in sideslip subsequent to an initial displacement in sideslip of 5° was calculated, with the use of a step-by-step procedure, for $\tau=0, 0.10, 0.20, 0.25, 0.287$, and 0.38 . The results are presented in figures 8 (a) to 8 (f). These figures indicate that as τ increases from 0 to 0.2 the period increases slightly, whereas the damping is markedly improved. The frequency of the oscillation is

FIGURE 9.—Effect of time lag on the period and damping of the lateral oscillation.

about $\omega=3.7$. However, as τ continues to increase, the presence of a high-frequency oscillation is noted in the motion since this oscillation becomes less damped and the low-frequency oscillation becomes more heavily damped. (See figs. 8 (d) and 8 (e).) For $\tau=0.38$, the motion is neutrally stable at the high frequency of $\omega=8.5$ but the low-frequency oscillation does not appear in this motion since it is very well damped. In figures 9 (a) and 9 (b), the period and damping of the lateral oscillation for several values of τ , calculated by the method discussed in this report, are compared with the period and damping readily obtained from the motion calculations shown in figures 8 (a) to 8 (f). The very good agreement between the results presented in figures 9 (a) and 9 (b) would probably be improved if the increment selected for the step-by-step calculations were reduced. The trends indicated by these results, however, are applicable only to the particular airplane-autopilot system considered in this example and may not be generalized to any other arbitrary airplane-autopilot system.

CONCLUDING REMARKS

A method is presented for determining the effect of time lag in an automatic stabilization system on the lateral oscillatory stability of an airplane. The method is applied to a typical present-day airplane equipped with an automatic pilot sensitive to yawing acceleration and geared to the rudder so that rudder control is applied in proportion to the yawing acceleration. The results calculated for an airplane-autopilot system by the method described are in good agreement with the airplane motions calculated by a step-by-step procedure.

APPENDIX

A METHOD FOR CONSTRUCTING CURVES OF CONSTANT PERIOD AND DAMPING AS A FUNCTION OF τ , AND h ,

If an over-all picture is desired of the effect of time lag for a given value of k_s or the effect of varying k_s for a given time lag, construction of curves of constant period and damping with the use of the following method is recommended.

The characteristic stability equation of the airplane-autopilot system (equation (5)) may be rewritten in the form:

$$\frac{A\lambda^4 + B\lambda^3 + C\lambda^2 + D\lambda + E}{-(A'\lambda^4 + B'\lambda^3 + C'\lambda^2 + D'\lambda)} = k_s e^{-\tau_s \lambda} \quad (A1)$$

If $\lambda = a + i\omega_s$ is substituted in each side of equation (A1), the condition that λ be a root of the characteristic equation is that the complex number $A_1 + iB_1$ obtained from the left-hand side must be equal to the one obtained from the right-hand side $A_2 + iB_2$. The quantities $A_1 + iB_1$ and $A_2 + iB_2$ may be represented by the expressions $R_1 e^{i\theta_1}$ and $R_2 e^{i\theta_2}$, respectively. Therefore, this requirement is equivalent to saying that $R_1 = R_2$ and $\theta_1 = \theta_2$ if λ is to be a root of equation (A1). If $\lambda = a + i\omega_s$ is substituted in the right-hand side, the following expressions result:

$$k_s e^{-\tau_s a} (\cos \tau_s \omega_s - i \sin \tau_s \omega_s) = A_2 + iB_2 = R_2 e^{i\theta_2}$$

where

$$R_2 = k_s e^{-\tau_s a}$$

and

$$\theta_2 = \tan^{-1} \frac{-\sin \tau_s \omega_s}{\cos \tau_s \omega_s} = -\tau_s \omega_s = 2\pi - \tau_s \omega_s$$

Therefore, if $\lambda = a + i\omega_s$ is substituted in the left-hand side and $A_1 + iB_1 = R_1 e^{i\theta_1}$ is obtained, the value of τ required to make $\theta_1 = \theta_2$ can be determined. Since τ_s is therefore determined and a is fixed, the value of k_s necessary to make $R_1 = R_2$ can be calculated. Thus for these values of k_s and τ_s ,

$$\lambda = a + i\omega_s$$

is a root of the transcendental stability equation (equation (5)).

For a given value of a , the analysis may be made throughout the range of ω_s and the corresponding values of k_s and τ_s determined. A curve representing this value of a may then be plotted as a function of k_s and τ_s . This procedure is repeated for a sequence of values of a and the corresponding curves in the k_s, τ_s plane are plotted. Each point on a curve of constant a represents a particular value of ω_s . Curves of constant frequency may therefore be plotted by drawing a curve through the given value of ω_s on each one of the a curves. The values of a and ω_s are converted to $T_{1/2}$ and P by equations (6). The final result would consist of curves of constant damping $T_{1/2}$ and curves of constant period P in the k_s, τ_s plane. Thus the effect of time lag on the lateral oscillations for any value of the gearing ratio k_s , or the effect of varying k_s for any value of time lag, may be ascertained. For purposes of illustration several lines of constant $T_{1/2}$ and P in the k, τ plane were calculated for the typical present-day airplane described in table I and are shown in figure 10.

A curve can be plotted in the k_s, τ_s plane which divides the quadrant into a satisfactory and an unsatisfactory region

FIGURE 10.—Several curves of constant period and constant damping for the typical present-day airplane described in table I.

according to any prescribed relationship between the period and damping of the lateral oscillation. In order to calculate this curve, several values of a and ω_s that exactly satisfy the criterion should be selected and substituted in equation (A1). The combination of k_s and τ_s is then obtained for each set of values of a and ω_s and the desired curve is plotted in the k_s, τ_s plane.

REPORT 1019

RELATION BETWEEN INFLAMMABLES AND IGNITION SOURCES IN AIRCRAFT ENVIRONMENTS¹

By WILFRED E. SCULL

SUMMARY

A literature survey was conducted to determine the relation between aircraft ignition sources and inflammables. Available literature applicable to the problem of aircraft fire hazards is analyzed and discussed herein. Data pertaining to the effect of many variables on ignition temperatures, minimum ignition pressures, minimum spark-ignition energies of inflammables, quenching distances of electrode configurations, and size of openings through which flame will not propagate are presented and discussed. Ignition temperatures and limits of inflammability of gasoline in air in different test environments, and the minimum ignition pressures and minimum size of openings for flame propagation in gasoline-air mixtures are included; inerting of gasoline-air mixtures is discussed.

The results of the survey indicate the possibility of reducing aircraft-fire hazards by:

- (1) Preventing contact of fuels or fuel vapors with the hot exhaust surfaces
- (2) Releasing an extinguishing agent inside of and around the exhaust system if a crash is imminent
- (3) Reducing the temperature of the exhaust duct or gases below the surface-ignition temperatures of gasoline and lubricating oil in the event of a crash
- (4) Increasing the surface-ignition temperatures of gasoline and lubricating oil
- (5) Using fuels of reduced volatility
- (6) Eliminating the electrical generating system as an ignition hazard in the event of a crash
- (7) Inerting the engine nacelles and wing compartments.

INTRODUCTION

As a part of the aircraft-fire-research program, a literature survey was conducted at the NACA Lewis laboratory during 1949-50 to determine the relation between inflammables and ignition sources. An effort has been made to correlate the limited data available with the problem of fire hazards in aircraft environments. The results of the survey are presented in three parts corresponding to the main sources of ignition in aircraft environments; that is, heated surfaces, electric sparks and arcs, and flames or hot gases.

The following variables have been considered in the ignition of fuels or fuel vapors by the different ignition sources:

Heated surfaces	Electric sparks and arcs	Flames or hot gases
Ignition temperature Mixture composition Ignition lag Mixture velocity Mixture turbulence Condition and composition of the ignition surface Ignition surface area Fuel composition Mixture pressure Effect of diluents	Type of spark Minimum spark-ignition energy Mixture composition Electrode spacing Electrode material and configuration Spark potential Spark duration Mixture velocity Mixture pressure Mixture temperature Effect of diluents	Mixture composition Mixture exposure duration Limiting size of openings for flame propagation Size, shape, and material of openings for flame propagation Mixture pressure Mixture temperature Effect of diluents

Although quantitative agreement among the large quantities of data in the literature is not to be expected because of the many different experimental techniques used, it is believed that comparison of the effects of the different variables as compiled herein will provide valuable information toward reducing aircraft-fire hazards.

I—IGNITION BY HEATED SURFACES

Although the data pertaining to the ignition of inflammable mixtures by heated surfaces are quite extensive, little agreement exists in technique, terminology, or results of various investigators. In the following discussions, an effort has been made to allow for different experimental techniques and to use a system of nomenclature presently acceptable in the combustion field.

TERMINOLOGY

IGNITION TEMPERATURES

The ignition temperature of an inflammable mixture is the minimum temperature to which the mixture must be raised in order that the rate of heat loss from the mixture is more than balanced by the rate at which heat is evolved from the mixture by exothermic chemical reaction. At this temperature, the reaction becomes self-accelerating and the temperature increases until self-propagating inflammation of the mixture occurs. A definite lag during which the reaction is self-accelerating thus exists, the magnitude of which is determined by the rapidity of acceleration of the reaction velocity. Defined in this manner, the ignition temperature of an inflammable is a mixture temperature and does not necessarily correspond to and may be considerably lower than the inflammation temperature or mixture temperature at the instantaneous appearance of flame. The ignition temperature of an inflammable, therefore, cannot be regarded

¹ Supersedes NACA TN 2227, "Relation Between Inflammables and Ignition Sources in Aircraft Environments" by Wilfred E. Scull, 1950.

as a physical constant, but must depend on the experimental conditions under which it is determined. Mixture composition, pressure, and temperature and the presence of catalysts or inhibitors, which accelerate or delay the reaction, are some of the variables affecting the lag before inflammation. The lowest temperature at which any quantity of inflammable will ignite is known as the minimum ignition temperature of the inflammable for the experimental method employed.

Efforts of various investigators to determine the ignition temperatures of inflammables have resulted in different methods of attaining the mixture temperature at which self-accelerating reaction begins. As a result of these experimental methods and the difficulties of determining the defined ignition temperature, many of the ignition temperatures reported in the literature are the temperatures of heated elements, which raise the mixture temperature to a level of self-accelerating reaction. These heated element temperatures are not necessarily the same as the ignition temperature of the mixture. In general, the temperatures reported hereinafter are specifically designated as to the temperature actually measured.

The most important methods employed to determine the ignition temperatures are as follows:

- (1) Crucible methods—static and dynamic
- (2) Dynamic heated-tube method
- (3) Adiabatic-compression method
- (4) Bomb method.

In all these methods, various criterions have been chosen as indications of ignition and inflammation. A sudden rapid pressure rise, an increase in temperature, or both, have been used as indications of ignition, whereas the appearance of flame or explosive sounds have been taken to indicate mixture inflammation.

The crucible methods (static or dynamic, depending on whether the supporting atmosphere in the crucible is quiescent or flowing) appear to be the most popular methods of determining the ignition temperatures of liquid inflammables. Also known as the oil-drop methods, the crucible methods are variations of a method described in references 1 and 2. Essentially, the method consists in dropping a drop of the inflammable liquid through an opening into a crucible fitted into a heated iron or steel block containing either quiescent or flowing air or oxygen. The crucible temperature and ignition lag are measured when the droplet bursts into flame. A precise knowledge of the exact mixture composition at the instant of ignition is unobtainable. Furthermore, the latent heat of vaporization of the droplet must be supplied by the system. In these methods, experimentally measured ignition temperatures are the temperatures of the heated crucible surfaces causing ignition.

The dynamic heated-tube method, which attempts to nullify the effect of enclosing surfaces, is described in reference 3. In this method, the flowing inflammable vapor and the supporting atmosphere are separately heated in concentric quartz or pyrex tubes. The inflammable vapor is metered into the supporting atmosphere in the large tube through a small orifice in the end of the small tube. In this case, the experimentally measured ignition temperature is the mixture

temperature at which inflammation occurs after a measured time lag. Such a method permits easy variation of the inflammable over-all mixture composition.

A description of the adiabatic-compression method of determining ignition temperatures is given in reference 4. In this method, the inflammable mixture of vapor and air or vapor and oxygen is suddenly compressed. Ignition occurs after a lag depending on the temperature reached by the compression process. The ignition temperature is computed from the experimentally measured compression ratio. This method is advantageous in that the mixture composition is known, accurate ignition-lag measurements are possible, and the relatively cold walls of the compression cylinder preclude any catalytic influence. Disadvantages of such a method are the large cooling losses, the difficulty of determining the exact value of the compression exponent γ , and the fact that the experimentally determined ignition temperature pertains to the compression pressure.

The bomb or heated-chamber method of determining ignition temperatures is described in reference 5. Essentially, the method consists in introducing an inflammable mixture into an evacuated chamber heated to a known temperature. The experimentally measured ignition temperature is taken as the chamber temperature that causes ignition after a measured ignition lag. Disadvantages of the method are the possible catalytic effects of the chamber surface and the heat required to increase the mixture temperature to the chamber temperature. Advantages of the method are the knowledge of the mixture composition and the ease with which normal-length ignition lags can be measured. Very small ignition lags are difficult to measure because of the time interval required to admit the mixture to the chamber.

The results of all these methods are affected by the experimental conditions and characteristics of the inflammables investigated. Some of the factors significantly affecting the experimentally determined ignition temperatures of inflammable substances are:

- (1) Fuel composition
- (2) Fuel-air or fuel-oxygen ratio
- (3) State of inflammable—vapor or liquid
- (4) Size of inflammable drop
- (5) Mixture pressure and temperature
- (6) Relative stagnation of mixture—turbulent or quiescent
- (7) Thermal conductivity of mixture
- (8) Ignition-lag period
- (9) Surface composition and physical character of ignition element
- (10) Surface area of ignition element
- (11) Surface-volume ratio of ignition chamber
- (12) Ignition-element temperature
- (13) Approach to ignition temperature—from mixture temperatures above or below ignition temperature
- (14) Method of introduction of inflammable to ignition element.

As a result of the effects of these variables on ignition temperature, the experimentally determined ignition temperature of an inflammable may be different in various sources of

information. Data from the same source, however, show the trends and the relative effects of different variables.

LIMITS OF INFLAMMABILITY

The limits of inflammability of a mixture, also known as the inflammation or explosive limits, are those proportions, generally volumetric, of fuel in air or oxygen that are just capable of self-propagation of flame throughout the entire mixture once inflammation has been initiated in a portion of the mixture. These limits are generally determined for upward, continuous self-propagation of a flame in a vertical tube of sufficient diameter such that the wall cooling effects are negligible. Mixtures just below the lower limits or just above the upper limits of inflammability may burn around the ignition source, but are incapable of propagating flame throughout the entire mixtures. In addition, the mixture volume must be large enough that the flame may still propagate even after the energy input required for the initial inflammation has been dissipated. For any particular inflammable, the limits of inflammability are affected by the direction of flame propagation, type of test apparatus, the amount of water vapor present in the mixture, and the mixture pressure and temperature.

Flame progress may be assisted or retarded by convection depending on whether the flame propagation is in an upward, horizontal, or downward direction; therefore a statement of the method of observation of the limits of inflammability is necessary. Generally, wider limits are found for upward than for downward flame propagation at atmospheric pressure and temperature. Data from reference 6 indicate that the lower and upper limits of inflammability of methane in air at atmospheric conditions, as determined for upward flame propagation, are increased and decreased, respectively, approximately 10 percent for downward flame propagation. Values reported herein are for upward flame propagation unless specified otherwise.

The effect of the type of test apparatus and the method of ignition used in the determination of the inflammability limits of various mixtures are minor. The inflammability range of several mixtures increased with increasing tube diameter up to a tube diameter of 2 inches, because of the decreased cooling effect of the walls. At atmospheric pressure, tube diameters greater than 2 inches have very little effect on the limits. In addition, literature indicates (reference 7) that inflammability limits are unaffected by the method of ignition—spark, flame, or fusion of a platinum wire.

The lower limit of inflammability of a mixture is only slightly affected by the amount of water vapor present in the normal atmosphere. Water-vapor presence reduces the upper limit because of displacement of oxygen by the water vapor. Because the amount of oxygen is important in an upper-limit mixture, the amount of inflammable capable of being ignited decreases with the decreased oxygen content, resulting in an over-all reduction of the upper inflammability limit.

The effect of varying mixture temperature on the downward propagation limits of inflammability of several mix-

tures is expressed in figure 1. The upper and lower limits of inflammability of the various mixtures decrease and increase, respectively, approximately linearly with decreasing mixture temperatures.

EXPERIMENTAL RESULTS IN PUBLISHED LITERATURE

Knowledge of the approximate temperature of heated surfaces capable of causing ignition is desirable because ignition of fire in aircraft may be caused by the exposure of inflammables to heated surfaces. Published experimental results for heated-surface ignition indicate the effects of a number of different variable experimental conditions. As far as possible, the results presented here are accompanied by data specifying the experimental conditions.

EFFECT OF MIXTURE COMPOSITION

Ignition temperatures.—The relative effect of mixture composition on the surface ignition temperatures of quiescent natural-gas-air mixtures ignited by single electrically heated nickel strips is shown in figure 2. The nickel strips of varying widths were mounted in the center of a chamber of 4½-cubic-foot capacity. The surface temperatures of the heated strips were measured by peened-in thermocouples. For the various widths of the heated ignition surfaces, the surface ignition temperature of the mixture increases approximately linearly with increasing proportions of natural gas in the mixture between the limits of inflammability. A few comparative experiments with methane in place of natural gas indicated that these mixtures ignited at approximately 30° F greater surface ignition temperatures than the natural-gas-air mixtures. Other investigations (reference 5, for example) indicated that the ignition temperatures of methane-air and natural-gas-air mixtures are lower than those of figure 2. This discrepancy is explained in reference 11 by the fact that the temperature of a heated ignition surface is greater than the true ignition temperature of the mixture. Although the ignition temperatures of methane-air and natural-gas-air mixtures increase with increasing proportions of fuel; the ignition temperatures decrease with increasing proportions of fuel for the higher hydrocarbons of the paraffin series. The

FIGURE 2.—Effect of mixture composition on surface ignition temperature of various quiescent natural-gas-air mixtures. Mixtures ignited by electrically heated nickel strips cut from same sheet of No. 18 B and S gage commercial nickel; length of strips, 4¼ inches. (Data from reference 11.)

FIGURE 3.—Effect of mixture composition on chamber ignition temperatures of various fuels at atmospheric pressure as determined by bomb ignition method except as shown.

chamber ignition temperatures of mixtures of the higher paraffin hydrocarbons and air decrease with increasing proportions of fuel within the range investigated (fig. 3). It might be expected from figure 3 that the ignition temperatures of mixtures of hydrocarbons and air might again increase with increasing richness of the mixtures. Although data from references 13 to 15 are erratic, it has been concluded by the authors that the ignition temperatures of individual mixtures of coal gas, benzene, toluene, methyl alcohol, S-1 fuel, and air, which are approximately constant over a wide range of fuel-air ratios, do increase eventually with increasing richness of the mixtures.

The ignition temperatures of gasoline mixtures, like the ignition temperatures of the higher paraffin hydrocarbons, decrease with increasing proportions of fuel within the range of data available (figs. 4 and 5). The effect of the proportions of fuel, oxygen, and nitrogen on the ignition temperatures of gasoline mixtures as determined by the dynamic heated-tube method is shown in these figures. Similar results are given in reference 13. Without exception, various fuels investigated singly in an engine at two engine speeds and with hot-spot ignition showed sharp increases in the ignition temperatures of lean mixtures.

Zones of ignition and nonignition.—Two types of ignition may exist for the same fuel for certain oxygen-fuel ratios: (1) A low-temperature ignition practically independent of fuel concentration or oxygen-fuel ratio; and (2) a high-

FIGURE 4.—Variation of mixture ignition temperature of gasoline with oxygen-fuel ratio for constant proportions of fuel. Method of ignition, dynamic heated tube; supporting atmosphere flow, 230 cubic centimeters per minute at atmospheric pressure and temperature. (Data from reference 16.)

temperature ignition varying markedly with these variables. The two types of ignition for gasoline-oxygen-nitrogen mixtures are indicated in figures 4 and 5. The ignition temperature of gasoline in air corresponds to the high-temperature

(a) Fuel, gasoline, 4.6 percent by volume.
(b) Fuels, 2,2,4-trimethylpentane, 3.8 percent by volume and *n*-octane, 4.3 percent by volume.
FIGURE 6.—Ignition characteristics of mixtures of fuel, oxygen, and nitrogen. Method of ignition, dynamic heated tube; supporting atmosphere flow, 230 cubic centimeters per minute at atmospheric pressure and temperature. (Data from reference 16.)

type of ignition. Dynamic crucible tests reported in reference 17 indicate that readily ignited hydrocarbons, such as cetane, heptane, decane, and decahydronaphthalene exhibit zones of nonignition above the minimum ignition temperatures. Similar results, presented in reference 18, indicate that mixtures of straight-chain paraffins, containing three or more carbon atoms and air exhibit zones of nonignition. Oxidation-resistant hydrocarbons, such as benzene, toluene, and 2,2,4-trimethylpentane exhibit no nonignition zone. Ignition and nonignition zones as determined by the dynamic heated-tube method are shown in figure 6 for mixtures of gasoline, normal octane, and isooctane (2,2,4-trimethylpentane) with oxygen and nitrogen. For a fixed proportion of inflammable, the minimum mixture ignition temperature is independent of the oxygen-fuel ratio. The isooctane-oxygen mixture does not exhibit zones of ignition and nonignition, but the ignition temperature of the mixture decreases slightly with increasing oxygen-fuel ratios.

FIGURE 7.—Variation of ignition temperatures of various fuels in air with ignition lag. Cetane and heptane were ignited at atmospheric pressure.

FIGURE 8.—Variation of compression ignition temperature of 1.42 percent by volume mixture of *n*-heptane and air with ignition lag. Method of ignition, adiabatic compression; final pressure, 176 pounds per square inch absolute. (Data from reference 4.)

The phenomenon of zones of nonignition may be due to the occurrence of low-temperature systems capable of cool-flame initiation. Research into the slow combustion of the higher hydrocarbons has shown that slow combustion reactions with accompanying incipient luminescence can be initiated at 300° to 400° F (reference 18). The luminescence increases with increasing temperatures until a cool flame appears. The cool flames move slowly about the reaction chamber, moving more slowly and becoming more diffuse with increasing temperature until they finally disappear leaving behind products of the incomplete combustion strongly aldehydic or peroxidic in character. At still higher

temperatures, ignition and complete combustion of the mixture is possible.

EFFECT OF VARYING IGNITION LAG

Ignition lag of quiescent mixtures.—The ignition temperature of inflammable mixtures also depends on the ignition lag or induction period between introduction of the mixture to the ignition source and the first indication of inflammation. The effect of ignition lag on the surface or chamber ignition temperature of various mixtures is expressed in figures 7 to 10. The ignition temperatures of the

inflammable mixtures decrease almost hyperbolically with increasing ignition lags. The minimum ignition temperatures of the mixtures occur when the ignition temperature no longer decreases with increasing time lag. The effect of ignition lag on the ignition temperature of a mixture of *n*-heptane and air as determined by the adiabatic compression method is shown in figure 8. Figure 9 indicates the effect of ignition lag on the surface ignition temperature of gasoline in flowing oxygen as determined using the dynamic crucible method. The ignition temperature of gasoline in flowing oxygen after a 1.5-second lag is approximately 608° F, whereas the minimum ignition temperature, corresponding to a lag of 25 seconds, is approximately 544° F. The influence of ignition lag on the chamber ignition temperature of aviation gasoline injected into four different heated steel configurations is shown in figure 10. The minimum ignition temperature of aviation gasoline as determined from these data is approximately 455° F.

Data, from reference 21, which illustrate the effect of ignition lag on the ignition temperature of aviation gasoline ignited by the heated chamber method when the fuel (4.2 percent by volume in air) was injected from the top into a vertical steel cylinder 12 inches in diameter and 12 inches in height, are given in the following table:

Ignition lag (sec)	Chamber ignition temperature (° F)
7	600
12	570
672	450

Ignition lag of mixtures ignited by heated spheres and rods.—Ignition of inflammable mixtures has also been effected by means of heated spheres shot into the mixture. The effect of the diameter of the heated sphere on the surface ignition temperatures of three fuel-air mixtures ignited by heated quartz and platinum spheres shot into the mixtures at an average velocity of 13.1 feet per second is shown in figure 11 (a). Ignition temperatures of the mixtures decreased with increasing sphere diameter because of the greater ignition area. The criterion for ignition used in reference 22 is the requirement that the initial rate of heat production by the reaction should be greater than the heat loss by conduction. Using this criterion the investigator concludes that the following is theoretically true for each initial sphere velocity:

$$\frac{2(T_s - T_o)}{d} = Ke^{-\frac{A}{RT_s}} \quad (1)$$

where

A apparent energy of activation of mixture

d diameter of sphere

K constant characterizing gas mixture and sphere material

R gas constant

T_o mixture temperature

T_s heated sphere temperature

(a) Experimental data.

(b) Reduced data.

FIGURE 11.—Effect of sphere diameter on surface ignition temperature of three fuel-air mixtures, at atmospheric pressure, ignited by heated quartz and platinum spheres shot into mixture at average velocity of 13.1 feet per second. (Data from reference 22.)

The data of figure 11 (a) have been replotted in figure 11 (b).

The same relative effect of velocity on the ignition temperatures of various inflammable mixtures is indicated in figure 12. The ignition source is at rest in this case and the mixture is in motion. The ignition temperature of the flowing mixture is the temperature of a rod situated in the center of a duct filled with flowing mixture and heated sufficiently to cause ignition of the mixture. The measured velocity is the velocity at the center of the duct. High mixture velocities correspond to short ignition lags; thus, the ignition temperature of an inflammable mixture increases with increasing velocity of the mixture.

The effect of variation of rod diameter on the ignition temperature of the mixture is expressed in figure 12 (b).

(a) Experimental data.

(b) Reduced data.

FIGURE 12.—Variation of surface ignition temperature of various fuels in air with gas-stream velocity. Ignition by $\frac{1}{4}$ -inch heated stainless-steel rods. Mixtures, stoichiometric at atmospheric pressure and temperature of 155° F. (Data from reference 23.)

For flowing mixtures ignited by heated metal rods, the following equation (reference 23) may be applied:

$$\frac{D}{V} e^{-\frac{E}{RB} \left[\frac{V}{D(T_r - T_o)} \right]} = C \quad (2)$$

where

B, C constants

D heated-rod diameter

E energy of activation of mixture

R gas constant

T_o flowing mixture temperature

T_r heated-rod temperature

V velocity of mixture flowing past heated rod

In cases of ignition of inflammable mixtures by both heated spheres and heated rods, the ignition effectiveness depends on the temperature of the ignition source, the size of the ignition source, and the duration of contact of the mixture with the ignition source. Factors related to these three criteria of ignition effectiveness are given in equation (2), which pertains to the ignition of flowing gas mixtures by heated metal rods. A factor that pertains to the duration of contact of the mixture with the ignition source is lacking in equation (1), which involves the ignition of quiescent gas mixtures by heated spheres shot into a mixture. This omission appears to be due to the author's criterion of ignition (reference 22) that recognized heat losses only by conduction.

Effect of turbulence.—Literature pertaining to the effect of turbulence on the ignition temperature of inflammable mixtures is not extensive. The available data contain no quantitative measurements of the amount of turbulence. Figure 13, which also includes the data of figure 2, indicates the effect of gentle turbulence excited by a small fan at the top of the ignition chamber on the ignition temperatures of natural-gas-air mixtures. Mild turbulence of a mixture decreases the mixture ignition temperatures. Subsequent investigation (reference 12), however, has contradicted this result. When the turbulence is sufficiently great, the

FIGURE 13.—Effect of mild turbulence on surface ignition temperature of various natural-gas-air mixtures. Mixtures ignited by electrically heated nickel strips cut from same sheet of No. 18 B and S gage commercial nickel. Length of strip, $\frac{3}{4}$ inches. (Data from reference 11.)

ignition temperatures are increased. According to figure 14, gentle stirring of an aviation-gasoline-air mixture increases the mixture ignition temperature approximately 30° F. Similar data have been found concerning the effect of mild turbulence on the ignition temperatures of stoichiometric mixtures of methane and oxygen, and hydrogen and oxygen.

FIGURE 14.—Influence of mild turbulence on chamber ignition temperature of aviation gasoline injected into top of steel cylinder, 6 inches in diameter and 36 inches high, at atmospheric pressure. (Data from reference 12.)

EFFECT OF SURFACE CONDITION AND COMPOSITION

Open plates in air.—Various data are available concerning the ignition of fuels dropped on heated metal plates in open air. Generally, the data indicate that the ignition temperature of an inflammable liquid is much higher when dropped on a heated metal plate in air than when dropped into a heated metal tube that confines the inflammable mixture to a high-temperature region. A comparison between the ignition temperatures of various liquid aircraft inflammables in these two environments is included in table I (a). The ignition temperatures of various inflammable liquids dropped on an electrically heated sheet-iron or nickel plate in air are presented in table I (b). According to reference 24, the same results were obtained by vaporizing the liquids and passing the vapor over the heated plates. Data from reference 25 indicate that the ignition temperatures of gasoline, gasoline-benzene mixtures, Diesel fuel, and motor oil placed on heated iron plates varied from 1325° to 1400° F, but were lowered to 1000° to 1025° F when copper plates were used. Droplets of lubricating oil at 750° F falling into a heated steel pipe were ignited at approximately 840° F, but Diesel fuel at a temperature of 425° F under the same conditions did not ignite below 1200° F. The low ignition temperatures of lubricating oils are assumed to be due to the greater instability of the complex molecules. Lowering of the ignition temperatures of the inflammable liquids by using copper plates may be due to the greater thermal conductivity of the copper and differences in the catalytic activity of the two surfaces.

Various investigators (reference 26) have indicated that heated surfaces in air, below temperatures of 950° F, do not present serious fire hazards when sprayed with small amounts of oil. Reference 27 indicates that oil explosions occur only

when oil vapor is confined to a high-temperature region. Drops of oil placed on a plate heated to 1400° F would not ignite, but oil vapor ignited at 750° F. Similar results are presented in reference 26, which indicate that lubricating oils will not spontaneously ignite when dropped on either bare open metal plates or thin asbestos mats heated to 950° F. Light fractions, such as gasoline, immediately formed a ball and gradually distilled away. Heavier oils also vaporized (probably accompanied by simultaneous cracking); the vapors were diluted by air so quickly that no ignition could occur.

The results of actual tests conducted with a Napier Lion reciprocating engine are given in reference 12. Aviation gasoline vapors confined within the exhaust pipe and exposed to exhaust-pipe temperatures of 570° F ignited after a lag of 13 seconds. Outside the exhaust pipe, aviation gasoline did not ignite below temperatures of 850° F. Lubricating oil ignited at exhaust-pipe temperatures of 625° F. This apparent controversy over the ignition temperatures of oil or gasoline ignited by heated surfaces is due to the fact that liquid oils or gasolines falling on heated metal plates in open air are idealized experimental conditions that allow rapid diffusion of the inflammable vapors. The higher ignition temperature for the aviation gasoline is probably due to the rapid local cooling of the exhaust pipe in contact with the rapidly evaporating liquid. Heated metal pipes, exhaust manifolds, or enclosed heated areas of an aircraft engine may confine the inflammable vapors to high-temperature regions for ignition-lag periods corresponding to low-temperature ignition.

Varying surface compositions.—The ignition temperatures of inflammable mixtures ignited by heated surfaces are affected by the composition and the condition of the ignition surfaces. The effect of the composition of the ignition surfaces on the surface ignition temperatures of natural-gas-air mixtures is shown in figure 15. The various steels, copper, and Monel metal do not differ in their ignition effectiveness as much as catalytically active platinum differs from nickel. The abnormal effect of molybdenum is probably associated with the rapid oxidation properties of the metal. In all the experiments with molybdenum strips, dense clouds of oxides were formed. Tungsten, however, which oxidizes readily at high temperatures, did not oxidize vigorously until raised to temperatures higher than those required for surface ignition of the natural-gas-air mixtures. The following data, from reference 19, indicate the effect of the ignition-surface composition on the surface ignition temperatures of gasoline as determined in air by the dynamic crucible method:

Disk material (in silica crucible)	Surface ignition temperature (° F)
Platinum.....	878
Iron.....	833
Copper.....	788

FIGURE 15.—Variation of surface ignition temperatures of natural-gas-air mixtures with percent of natural gas in mixture. Mixtures ignited by electrically heated metal strips. Size of metal strips, 4.25 by 0.50 by 0.04 inches. (Data from reference 11.)

Similar data are contained in table II concerning the effect of ignition-surface composition on the ignition temperatures of liquid fuels dropped into heated containers. In each case, catalytically inactive pyrex surfaces ignited inflammable mixtures at temperatures lower than those of metal surfaces. Discrepancies in ignition temperatures for the same substances in table II are probably due to different experimental techniques. Of the metal ignition surfaces with about the same degree of catalytic activity, those surfaces having the highest thermal conductivities had the lowest ignition temperatures. The effect of ignition-surface composition on the surface ignition temperatures of varying mixtures of a standard reference gasoline and benzene in air is indicated in figure 16. The ignition temperatures of the mixtures, excepting approximately 100-percent benzene, are 35° to 155° F greater for platinum surfaces than for quartz surfaces.

In similar experiments, the surfaces of greater catalytic activity or interstitial character must be hotter to ignite inflammable mixtures than surfaces of catalytic inactivity. Some references indicate that two types of combustion may be present in ignition by heated surfaces (1) a flameless, surface combustion, and (2) a gaseous combustion indicated by a flash. Combustion of a drop of liquid falling upon a surface that is not interstitial or porous in character or that is catalytically inactive occurs mostly in the gaseous phase with a minimum of surface combustion occurring. If the surface is highly catalytic or interstitial, however, it may be impossible for a flash to occur because most of the combustion may take place on the surface. Apparently, with all factors constant except the composition of the igniting surface, the surface ignition temperature of an inflammable mixture increases with increasing catalytic activity or interstitial character of the surface.

Rapid diffusion from the flameless reaction zones near the heated surfaces may explain the fact that higher surface ignition temperatures are required on catalytically active surfaces. Such rapid diffusion may diminish the concentration of fresh gas in the reaction zone below the limits for flame propagation at the surface temperature.

FIGURE 16.—Variation of surface ignition temperature of benzene-gasoline mixture in air at atmospheric pressure with various fuel compositions. Method of ignition, static crucible; ignition lag, 1 second. (Data from reference 28.)

The mixtures most difficult to ignite with the catalytically active platinum strips are the mixtures having approximately stoichiometric fuel-air ratios. With platinum ignition surfaces, the combustion products are almost completely oxidized, and the greatest thermal energy of the reaction occurs with mixtures of approximately stoichiometric fuel-air ratios. The thermal energy of the reaction accounts for the extremely high ignition temperatures of near stoichiometric mixtures of natural gas and air ignited by heated platinum surfaces. No effect of surface composition on the ignition temperatures of the three mixtures ignited by shot-in spheres of quartz or platinum is apparent in figure 11. Compared with platinum, quartz is catalytically inactive. The mixture composition in each case, however, is less or greater than the stoichiometric fuel-air ratio for each particular mixture; the mixtures are probably too far from the stoichiometric fuel-air ratios to be greatly affected by the composition of the ignition surface.

Varying surface conditions.—All the common metals having high melting points ignite inflammable mixtures with about equal facility except those on the surface of which scale or ash is formed. This scale or ash forming tendency is especially peculiar to iron. A possible explanation is that scale or ash upon a surface forms an insulating coating, which requires the surface to be heated to a much higher temperature for ignition than would otherwise be necessary. A gas film or layer on the inside of a container may act in the same manner.

According to reference 29, a stoichiometric mixture of methane and air introduced into a silica cylinder etched inside with hydrofluoric acid and maintained in a vacuum for 15 minutes ignited at 1085° F. The same mixture, placed in the cylinder following the evacuation of water vapor or carbon dioxide vapor, ignited at 1265° F. The surface ignition temperature of the mixture was increased by the adsorbed film of water vapor or carbon dioxide vapor.

EFFECT OF VARYING IGNITION SURFACE AREA

Heated plates.—Because the thermal energy required for ignition of an inflammable mixture is essentially constant, increasing the area of heat transfer results in a decrease of the surface temperature required for ignition of an inflammable mixture. This effect on a quiescent 7-percent mixture of natural gas in air ignited by electrically heated nickel surfaces is indicated in figure 17. From figure 17, it is apparent that a minimum surface ignition temperature exists for the mixture and this minimum ignition temperature cannot be decreased by indefinitely increasing the area of the ignition surface.

Heated wires.—Very fine wires electrically heated to incandescence may cause inflammation of explosive mixtures; but ignition of a methane-air mixture by an electrically heated platinum or tungsten wire is possible only in a narrow range of heating currents. Below this current range, flameless surface combustion occurs; above this range, the wires fuse without igniting the mixture. According to reference 30, the ignition of inflammable mixtures by heated platinum wires is not due to ionization, but to heat transfer alone, because ions do not appear until flame appears and no ions are formed during the flameless surface combustion.

Because of heat generated on its surface by flameless combustion, an electrically heated platinum wire surrounded by an inflammable mixture has a higher temperature than when surrounded by air. The mixture near the wire becomes heated and convection currents are set up. Ignition of the mixture occurs only if a portion of the mixture remains in contact with the heated wire for a period of time greater than the ignition lag. The convective effect is greatest with the mixtures having the highest thermal energies; that is, mixtures having compositions near stoichiometric fuel-

air ratios (reference 31). Thus stoichiometric mixtures are in contact with the heated wires for the shortest periods of time and consequently have higher ignition temperatures than mixtures of other compositions. The ignition temperatures of the mixtures decrease with increasing diameter of the heated ignition wires, because of the greater ignition area.

In the investigation of flameless surface combustion reported in reference 32, 0.02 to 0.09 cubic centimeter of hexane, cyclohexane, cyclohexene, and benzene were separately introduced into an air atmosphere in a 400-cubic-centimeter cylinder heated to 221° F that contained a small electrically heated platinum wire. Heating of the wire to 572° F resulted in sudden increases of the wire temperature for a short period of time prior to inflammation of the mixtures. According to reference 31, small, heated tungsten wires exposed to inflammable mixtures are quickly oxidized and burst into flames immediately at high wire temperatures. The ignition of the mixture is caused by flames rather than by a heated surface.

Data obtained from reference 33 indicate that the limiting minimum diameters of heated wires capable of igniting inflammable methane-air mixtures are approximately 0.0079 and 0.0354 inch for platinum and iron wires, respectively. For wires of lesser diameters than these, it is assumed that a layer of oxygen molecules forms on the heated wire, and thermal energy sufficient to ignite the mixture cannot be conducted through the layer. Even in an unburned mixture of methane and air, a spiral piano wire heated to redness has been found to oxidize.

Heated particles.—Ignition of inflammable mixtures by small heated spheres shot into the mixture has already been discussed. Friction sparks and fusion sparks both fall into the category of small heated particles.

According to reference 34, although natural-gas-air mixtures can be ignited by friction sparks, it is improbable that natural gas can be ignited in the field by friction sparks. Reference 35 indicates that explosive mixtures of gasoline vapors and air at atmospheric pressure and temperatures of 70° to 120° F would not ignite when exposed to sparks produced by the impact breaking of piano wire, contact of two pieces of hardened steel, steel in contact with a rotating emery wheel, or sparks from red-hot steel. Such sparks ordinarily lack the thermal energy required to ignite inflammable mixtures. Ordinary white friction sparks produced by grinding steel in air are actually small metal particles, which oxidize or burn in air after being initially heated by being torn off in the grinding process. These sparks will not ignite petroleum vapors unless the metal is held to the wheel for a long time to preheat the metal and thereby increase the thermal energy of the spark. Alloy steel, in general, produces red friction sparks of low temperature, whereas some special alloys such as are used in cigarette lighters produce bright white sparks capable of igniting gasoline. Fusion sparks are small fused-incandescent particles derived from metals contacting wires through which current is passing. Because the ignition temperature of a mixture ignited by small heated particles increases rapidly with decreasing particle diameter, fusion sparks ordinarily are very feeble ignition sources.

FIGURE 17.—Effect of surface area on surface ignition temperature of quiescent 7-percent mixture of natural gas and air. Ignition surface, electrically heated nickel. (Data from reference 11.)

EFFECT OF VARYING FUEL COMPOSITION

The ignition temperature of an inflammable mixture varies with the type of fuel and the amount of antiknock additives in the fuel. This report is primarily concerned with the effect of gasoline composition on ignition temperatures, but the effect of hydrocarbon families in addition to those that appear in gasoline are also included.

The variation of surface ignition temperature with the number of carbon atoms present per molecule for different hydrocarbon families is shown in figure 18. Under the same experimental conditions, the ignition temperatures of *n*-paraffin hydrocarbons decrease with a lengthening of the carbon chain, with the shortest chain hydrocarbons having the highest ignition temperatures. Iso-paraffins have higher ignition temperatures than the *n*-paraffins (fig. 18 (a)). The ignition temperatures of aromatic hydrocarbons are also higher than those of *n*-paraffins.

The surface ignition temperatures of various hydrocarbons are expressed as functions of the boiling temperatures in figure 19. Although the absolute value of the ignition temperature for the same hydrocarbon differs with the reference,

FIGURE 19.—Effect of boiling temperature on surface ignition temperatures of several fuels in air at atmospheric pressure.

trends are similar for the same hydrocarbon families. The effect of fuel composition on the surface ignition temperatures of mixtures of isooctane and heptane ignited in air on a platinum surface by the static crucible method is shown in figure 20. In reference 38, it is stated that no exact relation exists between the octane number and the ignition temperature of a fuel, but figure 20 and table III indicate that the ignition temperatures of unleaded fuels generally increase with increasing octane number.

FIGURE 20.—Effect of varying fuel composition on surface ignition temperatures of *n*-heptane—iso-octane (2,2,4-trimethylpentane) mixture as determined in air at atmospheric pressure. Method of ignition, static crucible; ignition surface, platinum; ignition lag, 1 second. (Data from reference 28.)

FIGURE 21.—Effect of cetane number on surface ignition temperature of various fuels in air at atmospheric pressure. Cetane numbers are converted A.S.T.M.-CFR numbers.

The ignition temperatures of unleaded fuels in air are also generally increased by additions of tetraethyl lead. Table IV shows the effect of additions of tetraethyl lead on the ignition temperatures of several fuels. A relation exists between the cetane numbers and the surface ignition temperatures of various fuels, as indicated by figure 21. The cetane numbers of the fuels were converted from octane numbers, given in reference 41, by the method given in reference 42. The ignition temperatures of the various fuels increase with decreasing fuel quality or cetane number.

EFFECT OF VARYING PRESSURE

Increased pressure decreases the ignition temperatures of inflammable mixtures. The effect of pressure on the ignition temperatures of various hydrocarbons is shown in figures 22 to 24. The chamber ignition temperature of gasoline in air

FIGURE 22.—Effect of mixture pressure on mixture ignition temperature of methane in air. Method of ignition, dynamic heated tube. (Data from reference 3.)

FIGURE 23.—Effect of mixture pressure on chamber ignition temperatures of several fuels and oils in air. Method of ignition, bomb. (Data from reference 43.)

as determined by the bomb method without spraying decreases from approximately 705° F at a pressure of 2.2 atmospheres to approximately 450° F at 10 atmospheres (fig. 24).

EFFECT OF DILUENTS

Figures 4 and 5 indicate the effect of nitrogen as a diluent on the mixture ignition temperatures of inflammable mixtures ignited by the dynamic heated-tube method. The ignition temperatures of the mixtures increase with decreasing amounts of oxygen. This effect is in general agreement with the statement that the ignition temperatures of fuels are generally less in oxygen than in air. In the low ignition-

FIGURE 24.—Variation of chamber ignition temperature of gasoline in air with air pressure. Method of ignition, bomb. (Data from reference 43.)

temperature range of figures 4 and 5, however, the effect of inert gases is negligible. Regardless of the percentage of inert gas in the mixture, the ignition temperature in the low ignition-temperature range is approximately constant.

The ignition temperatures and limits of inflammability of gasoline and lubricating oils are dependent on the conditions and methods of experiment; these properties of gasolines and lubricating oils as obtained by different investigators are included in tables V and VI.

II—IGNITION BY ELECTRIC SPARKS AND ARCS

A study of ignition of inflammable mixtures by electric sparks and arcs involves an understanding of the nomenclature of spark-ignition systems. Definitions of terms encountered in the contemporary literature, which pertain to electric spark and arc ignition, are presented in the following paragraphs.

TERMINOLOGY

CAPACITANCE SPARKS

Capacitance sparks are produced by the discharge of charged condensers. According to reference 44, capacitance

sparks are usually bright, may be of short duration, and exhibit a spectrum that corresponds to the spectrum of the gas mixture in which the spark occurs. The current in a capacitance spark may be very large; however, the total energy transferred in the spark may be small because of the short duration of the spark. The total energy of a capacitance spark, expressed as the energy required in a circuit to produce the spark, is

$$E = \frac{1}{2} C (V_2^2 - V_1^2) \quad (3)$$

where

C capacitance of discharged condenser, farads

E energy dissipated in spark, joules

V_1 extinction potential remaining after spark has been dissipated because of weakening of field and depletion of ions, volts

V_2 circuit potential immediately prior to spark, volts

Generally, the extinction potential V_1 is so small that it can be disregarded. If V_2 is very small, however, V_1 may be important. Considerable energy losses may occur in the electric circuits through skin effects in the condenser plates and conductors especially if solid dielectrics are used. For this reason, it has been recommended that air condensers be used in electric circuits to determine the minimum spark-ignition energies of incendiary capacitance sparks.

INDUCTANCE SPARKS

Also known as low-tension sparks, inductance sparks are often obtained by breaking a wire in an inductive electric circuit or from magnetos or ignition coils. These sparks are generally not as bright in appearance as capacitance sparks and exhibit a spectrum corresponding to the spectrum of the vapor of the metal electrodes. The duration of inductance sparks can be relatively long compared with the duration of capacitance sparks; the total electric energy transferred in such sparks may therefore be large. Like the capacitance spark, the energy dissipated in an inductance spark is difficult to measure, but can be expressed as,

$$E = \frac{1}{2} L i^2 \quad (4)$$

where

E energy dissipated in spark, joules

i current in circuit prior to spark, amperes

L inductance of electric circuit, henrys

According to reference 44, the total energy dissipated in the spark may be less or greater than $\frac{1}{2} L i^2$. If the spark is extinguished before the available electromagnetic energy is dissipated, the total energy dissipated in the spark will be less than $\frac{1}{2} L i^2$. The total energy dissipated in the spark may be greater than $\frac{1}{2} L i^2$ if the potential across the break is enough to maintain the spark.

FUSION SPARKS

Fusion sparks are small incandescent particles and are treated in the section IGNITION BY HEATED SURFACES.

MINIMUM SPARK-IGNITION ENERGY

The minimum spark-ignition energy of an inflammable mixture is the total electric energy stored in an electric circuit at the initiation of the weakest spark just capable of ignition of the mixture. Essentially, this energy is the energy transmitted to the gas between the electrodes as heat and ionization.

QUENCHING DISTANCE

The quenching distance of any electrode configuration is the minimum electrode spacing below which the reaction initiated in a hydrocarbon-air mixture by an incendiary spark is quenched.

The amount of energy in any of the different type sparks

FIGURE 25.—Effect of mixture composition on minimum spark-ignition energy and quenching distance of methane-air mixtures at temperature of 77° F and pressure of $\frac{1}{3}$ atmosphere. (Data from reference 45.)

is difficult to measure exactly. Most of the results are therefore reported as the energy required in an electric circuit capable of producing an incendiary spark. This report is concerned with the minimum spark-ignition energy required to ignite a gasoline-air mixture and the minimum electrode spacing below which the reaction initiated in a gasoline-air mixture by an incendiary spark is quenched. These data are not extensive in the literature; however, knowledge pertaining to the spark ignition of the lighter hydrocarbons is quite extensive, and many of these results are included herein.

The spark-ignition process has been defined as an ionization process, a thermal process, or a combination of the two processes. Regardless of the definition of the type of process, the minimum spark-ignition energy of an inflammable mixture depends on mixture composition, pressure, temperature, velocity, spark duration, and electrode size, material, spacing, and configuration. Ignition lag, when applied to spark ignition, is approximately zero, because of the high temperature of the spark.

FIGURE 26.—Effect of mixture composition on minimum spark-ignition energy of benzene-air and natural-gas-air mixtures at room temperature and pressure of 1 atmosphere. Spherical stainless-steel electrode configurations. (Data from reference 46.)

EXPERIMENTAL RESULTS IN PUBLISHED LITERATURE

The ignition of fires in aircraft by electric sparks and arcs depends generally on the energy available in the spark. Whether the spark-ignition energy is capable of ignition depends on various experimental conditions. The manner in which results are presented here is similar to the manner in which heated-surface ignition results were presented; that is, the results are accompanied by data specifying the experimental conditions.

CAPACITANCE SPARKS

Effect of mixture composition.—The effect of mixture composition on the minimum spark-ignition energy of several different quiescent mixtures ignited by sparks from different electrode configurations is shown in figures 25 and 26. The curve of minimum spark-ignition energy, plotted against mixture composition for a methane-air mixture at a temperature of 77° F and a pressure of $\frac{1}{2}$ atmosphere (fig. 25), passes through a minimum of approximately 1.7 millijoules at approximately 8.4 percent by volume of methane in air, when $\frac{1}{16}$ -inch stainless-steel electrodes embedded in 1-inch glass disks are used. Similar values for other mixtures are given in the following table for an approximate temperature of 77° F and pressure of 1 atmosphere. Stainless-steel electrodes were used except for methane, which was investigated by using stainless-steel electrodes embedded in 1-inch glass disks.

Inflammable	Mixture vapor in air, (percent by volume)	Electrode diameter (in.)	Electrode configuration	Electrode spacing (in.)	Least energy (millijoules)	References
Benzene.....	3.85	$\frac{1}{16}$	Spherical.....	0.05	0.4	46
Benzene.....	3.85	$\frac{1}{16}$	Spherical.....	.05	1.7	46
Natural gas.....	8.00	$\frac{1}{16}$	Spherical.....	.10	0.4	46
Natural gas.....	8.40	$\frac{1}{16}$	Spherical.....	.05	2.0	46
Methane.....	10.00	$\frac{1}{16}$	Hemispherical.....	---	0.7	47

For each of these inflammable mixtures, well defined upper and lower limits of inflammability exist.

The data given in the following table (reference 48) indicate that the minimum spark-ignition energies of different quiescent hydrocarbon-air mixtures at 77° F and pressure of 1 atmosphere ignited by capacitance sparks from the same electrode configuration do not differ greatly:

Inflammable	Percent of fuel in fuel-air mixture by volume	Least energy (millijoules)
Methane.....	8.45	0.28
Ethane.....	6.61	.25
Propane.....	5.07	.26
n-Butane.....	4.53	.26
n-Hexane.....	3.64	.24
n-Heptane.....	3.36	.25
Cyclopropane.....	6.34	.18
Cyclohexane.....	3.94	.24
Benzene.....	4.67	.21
Diethyl ether.....	5.30	.19

The effect of mixture composition on the minimum spark-ignition energies of flowing propane-air mixtures at a pressure of 3 inches of mercury absolute is indicated in figure 27. The general shapes of the curves, for the three mixture velocities plotted, are much the same as the shapes of curves for various quiescent mixtures.

FIGURE 27.—Effect of mixture composition and velocity on minimum spark-ignition energy of flowing propane-air mixtures at temperature of 80° F and pressure of 3 inches mercury absolute. Electrode spacing, 0.25 inch; capacitance-spark duration, 600 to 900 microseconds. (Data from reference 49.)

Effect of electrode spacing.—The effect of varying electrode spacings of different electrode configurations on the minimum spark-ignition energies of various inflammable mixtures is shown in figure 28. A critical electrode spacing exists for each electrode configuration. The minimum spark-ignition energy required to ignite a mixture is approximately constant for electrode spacings greater than the critical spacing. Greatly increased electrode spacings or spacings less than the critical spacing increase the required minimum spark-ignition energy of a mixture. According to reference 45, the critical electrode spacing represents the spacing below which the chemical reaction initiated by the initial inflammation is quenched by the cooling effect of the spark electrodes and is analogous to the diameter of the largest tube through which flame will not propagate. The minimum spark-ignition energies of a stoichiometric mixture of natural gas and air are approximately 0.45 millijoules for electrode spacings greater than the critical spacing or quenching distance of approximately 0.08 inch for two electrode configurations. When the electrode spacing is decreased to less than the quenching distance, the minimum spark-ignition energy increases gradually if rounded electrodes are used and abruptly if rounded electrodes embedded in glass are used. The abrupt change in the case of the disk electrode configuration may be due to the large cooling area of the glass disks. The quenching distance of one electrode configuration varies with composition of a methane-air mixture at a temperature of 77° F and a pressure of $\frac{1}{2}$ atmosphere, as indicated in figure 25. A quenching distance of approximately 0.089 inch exists for a glass-disk electrode configuration igniting a 9 percent (by volume) mix-

ture of methane and air at a temperature of 77° F and atmospheric pressure (reference 50).

Under the same atmospheric conditions, 1/2-inch spherical stainless-steel electrodes and 3/16-inch hemispherical brass electrodes have exhibited quenching distances of approximately 0.053 inch in the spark ignition of approximately 8.5 percent by volume mixtures of natural gas and air and

(a) Fuel, natural gas; data from reference 45.

(b) Fuel, Pittsburgh natural gas; data from reference 46.

(c) Fuel, methane; data from reference 44.

FIGURE 28—Continued.

methane and air, respectively (fig. 28 (b) and 28 (c)). Quenching distances increase with increasing electrode size and thermal conductivity of the electrode material, owing to the increased cooling effect. Increasing the electrode size and electrode spacing for the same inflammable mixture increases the minimum spark-ignition energy required to ignite the mixture, because of the larger cooling area. For the same reason, the inflammability range is smaller when determined with large electrodes than with small ones (fig. 26).

Effect of electrode material and configuration.—With the exception of the relative effect of varying the thermal conductivity of the electrodes, varying the electrode material has no significant effect on the ignition of inflammable mixtures by capacitance sparks. Ignition of gaseous mixtures by sparks from platinum, nickel, zinc, aluminum, lead, brass, and steel electrodes was unaffected by changes in the electrode material (references 44 and 51). Ignition of the mixture was affected by the changes in electrode configuration.

Effect of spark potential.—Generally, the minimum spark-ignition energy of an inflammable mixture is practically independent of the spark potential of capacitance sparks. The same spark-ignition energy, regardless of the potential and capacitance changes in the circuit, ignites mixtures of the same composition. Some references indicate that the minimum spark-ignition energy required to ignite an inflammable mixture decreases with increasing spark potential. These data are insignificant in accordance with the results reported

in reference 50. When the sparking potential of capacitance sparks was varied from 1.6 to 5.8 kilovolts the minimum spark-ignition energies required to ignite methane-air mixtures was relatively unaffected by potential variations. Most of the references agree that it is the electrode configurations and electrode spacings that determine the minimum spark-ignition energies of capacitance sparks capable of igniting inflammable mixtures.

Effect of mixture velocity and spark duration.—According to reference 49, the minimum spark-ignition energy required to ignite flowing propane-air mixtures at low pressures increases approximately linearly with mixture velocity. This phenomenon is graphically shown in figure 29 for a 5.2 percent by volume mixture of propane in air at pressures of 2, 3, and 4 inches of mercury absolute. The relatively high ignition energies are due to the very low mixture pressures.

Minimum spark-ignition energies of flowing propane-air mixtures increase with spark duration as shown in figure 30. The relation is not linear, being approximately of the form

$$E = Kt^n \quad (5)$$

where

E minimum spark-ignition energy

K constant

n constant < 1

t spark duration

FIGURE 29.—Effect of mixture velocity and pressure on minimum spark-ignition energy of flowing 5.2 percent by volume mixture of propane in air at temperature of 80° F. Electrode spacing, 0.25 inch; capacitance-spark duration, 600 to 800 microseconds. (Data from reference 49.)

FIGURE 30.—Effect of capacitance-spark duration on minimum spark-ignition energy of flowing 5.2 percent by volume mixture of propane in air at temperature of 80° F. Electrode spacing, 0.25 inch. (Data from reference 49.)

Electrostatic sparks.—Electrostatic sparks are a special type of capacitance spark. Electrostatic charges capable of spark production can be accumulated by friction, impact, pressure, cleavage, induction, successive contact and separation of unlike surfaces, one of which is generally an insulator, and transference of inflammable fluids and gases from one container to another. Air temperatures appear to have no significant effects on the charges accumulated, but increasing humidity tends to prevent accumulation of high potential electrostatic charges. The potential of electrostatic charges accumulated by liquids flowing in tubes decreases with decreasing liquid pressures.

INDUCTANCE SPARKS

Effect of mixture composition.—The effect of mixture composition on the minimum spark-ignition energies of inductance sparks is indicated in figure 31 for two hydrocarbon-air mixtures. Because the electric circuit inductance is difficult to measure, the results are expressed as the minimum ignition current with a constant electrode spacing. The effect of mixture composition is approximately the same for inductance sparks as for capacitance sparks. Well-defined limits of inflammability exist with both types of igniting spark. Approximately 0.59 ampere primary current in the inductive circuit produces a spark capable of igniting an 8.3 percent by volume mixture of methane in air. An ignition current of approximately 0.475 ampere in the same electric circuit will produce an inductive spark capable of igniting a 4.2 percent by volume mixture of *n*-butane in air. These data were obtained at atmospheric pressure and temperature. According to available data, the ranges of inflammability determined for capacitance sparks are slightly greater than those determined for inductance spark ignition.

Effect of electrode spacing.—Because of the manner in which inductance sparks often occur, few data are available that indicate the effect of electrode spacing on the ignition of inflammable mixtures. The variation of spacing of inductance-

FIGURE 31.—Effect of mixture composition on minimum ignition currents of primary circuits producing inductance sparks capable of igniting methane-air and *n*-butane-air mixtures at atmospheric pressure and temperature. Electrode spacing, 0.0394 inch. (Data from reference 52.)

spark electrode configurations with mixture composition is indicated in figure 32 as being similar to the variation with capacitance-spark electrode configurations. A minimum electrode spacing of approximately 0.043 inch is indicated for an 8.5 percent by volume mixture of methane in air ignited by inductance sparks from the particular electrode configuration.

Effect of electrode material.—Unlike the effect of electrode material on capacitance-spark ignition, the minimum spark-ignition energies of inflammable mixtures ignited by inductance sparks are affected by material changes in the electrode configuration. Ethane-air and carbon-monoxide-air mixtures were ignited at atmospheric temperature and pressure using electrodes of platinum, nickel, copper, aluminum, and iron (reference 54). Decreasing density of the electrode material generally increased the ignitibility of the inflammable mixtures. The least amount of energy dissipated in an inductive spark capable of igniting an inflammable mixture occurs with spark electrodes of the lightest metal.

FIGURE 32.—Effect of mixture composition on minimum spacing of electrode configuration producing inductance sparks capable of igniting methane-air mixtures at atmospheric pressure and temperature. Electrode configuration, 0.394-inch-diameter platinum disk and sharply pointed platinum cone; primary circuit current, 1.0 ampere. (Data from reference 53.)

Effect of circuit inductance and potential.—The energy required for ignition of an inflammable mixture by inductance sparks depends on the inductance, the current, and the potential in the electric circuit prior to the spark. The amount of energy required to ignite the mixture is substantially constant, but larger amounts of energy may be indicated if a large portion of the measured energy is dissipated in the inductance coil as core losses. The following data from reference 55 indicate the effect inductance and current in an electric circuit have on the measured minimum spark-ignition energy required to ignite a mixture of coal gas and air at atmospheric pressure and temperature.

Number of layers in inductance-coil winding	Core of coil	Circuit inductance (henrys)	Circuit current (amperes)	Spark-ignition energy (millijoules)
14	Air	0.01	0.35	0.6
14	Straight iron bar	.07	.15	.8
14	Rectangular iron frame	.56	.09	2.3

Inductance sparks from electric circuits of low potential require more measured spark-ignition energy to ignite the same inflammable mixture than inductance sparks from similar electric circuits of higher potential, as indicated by the following data from reference 56 for inductance-spark

ignition of an 8.5 percent by volume mixture of methane in air at atmospheric temperature and pressure.

Circuit potential (volts d. c.)	Circuit inductance (henrys)	Circuit current (amperes)	Spark-ignition energy (millijoules)
4	0.02144	0.77	6.35
220	.02144	.35	1.30
4	.012	1.025	6.30
220	.012	.4	.96

The amount of energy dissipated in an inductance spark consists of two parts: the energy stored in the electric circuit prior to the spark and the continued supply of energy from the circuit potential. The amount of energy stored in the electric circuit prior to the inductance spark is the only spark-ignition energy measured. The spark-ignition energy supplied by the electric circuit potential to an inductance spark increases with increasing circuit potential. Thus, inductance sparks from electric circuits of low potential require greater measured amounts of spark-ignition energy $\frac{1}{2}Li^2$ than sparks from circuits of high potential to ignite similar inflammable mixtures.

Effect of type of current in circuit.—The type of current in the electric circuit, alternating or direct, has no significant

FIGURE 33.—Effect of mixture composition on minimum ignition pressures of methane-air mixtures at temperatures of 78° to 87° F. Method of ignition, bomb; electrode configuration, spark-plug; electrode spacing, 0.110 inch; capacitance-spark ignition energy, 8640 millijoules; volume of bomb, 750-cubic-centimeters. (Data from reference 58.)

effect on the ignition ability of inductance sparks. No difference in the ignition ability of alternating or direct-current inductance sparks has been found by the investigators of reference 57, who ignited fire-damp—air mixtures at atmospheric pressure and temperature. The following data from reference 56 indicate the negligible effect of current type on the incendiarity of inductance sparks igniting an 8.5-percent (by volume) methane-air mixture at atmospheric conditions:

Type of current	Current frequency (cps)	Ignition current (amperes)
Direct.....	---	0.415
Alternating.....	68	.410
Alternating.....	200	.420

EFFECT OF GAS PRESSURES AND TEMPERATURES

The effects of temperature and pressure are the same for both capacitance and inductance sparks; the following discussion therefore applies to all sparks.

Varying pressure.—The ignition of inflammable mixtures is significantly affected by varying mixture pressures and temperatures. The inflammability range of different mix-

FIGURE 34.—Effect of mixture composition on minimum ignition pressures of *n*-butane-air mixtures at temperatures of 73° to 84° F. (Data from reference 58.)

FIGURE 35.—Effect of mixture composition on minimum ignition pressures of two fuel-air mixtures.

tures is reduced by decreasing mixture temperatures and pressures. This effect of mixture pressure on the limits of inflammability of several inflammable mixtures is shown in figures 33 to 35. The minimum ignition pressure or the minimum mixture pressure of methane below which ignition

is no longer possible, exists at mixture compositions less than stoichiometric; reference 58 indicates that the same relation is true for hydrogen. The minimum ignition pressures of heavier hydrocarbons, such as propane and *n*-butane, occur at mixture compositions greater than stoichiometric. These phenomena may be due to the diffusivity of air being less than the diffusivities of methane or hydrogen, but greater than those of propane or *n*-butane. The minimum ignition pressures do not vary greatly for hydrocarbons in the range of molecular weights given in the following table taken from reference 58 which gives the minimum ignition pressures of hydrocarbon-air mixtures as determined in a 750-cubic-centimeter metal bomb (mixture temperature, 75° to 85° F; electrode spacing, 0.110 inch; capacitance-spark ignition energy, 8640 millijoules).

Hydrocarbon	Minimum ignition pressure (mm Hg abs.)
Hydrogen.....	11.5
Methane.....	19.0
Butadiene-1,3.....	21.0
Butenes-2.....	29.0
<i>n</i> -Butane and iso-butane.....	29.0
Benzene.....	28.0
2,4-Dimethyl-1,3-pentadiene.....	33.0
<i>n</i> -Nonane.....	33.0

Various investigators have found higher minimum ignition pressures for different hydrocarbons, as indicated in figure 35 (a), for natural gas. Differences in results are due to different experimental techniques. Little data expressing the effect of varying mixture pressures and temperatures on the incendiary properties of gasoline-air mixtures are available.

According to reference 60, the minimum ignition pressure of various gasoline-air mixtures ignited in vessels of 0.425, 1.09, and 125.0 cubic-foot capacity by sparks or hot platinum wires is 33 millimeters of mercury absolute at ordinary ambient temperatures. Close agreement with these results is evident in figure 35 (b). The minimum ignition pressure of mixtures of 100-octane gasoline and air ignited by four different methods at atmospheric temperatures is 35 milli-

FIGURE 36.—Effect of mixture pressure of 8.5 to 9.5 percent by volume mixture of methane and air at temperature of 77° F on quenching distance of one electrode configuration. (Data from reference 50.)

meters of mercury absolute for a 1.75 percent by volume mixture of gasoline in air. The lower and upper limits of inflammability of 100-octane gasoline and air mixtures are relatively unaffected by mixture pressure changes above 60 and 300 millimeters of mercury absolute, respectively.

FIGURE 37.—Effect of electrode spacing on minimum ignition pressures of two fuel-air mixtures at temperatures of 70° to 75° F. Ignition by spark-plug-electrode configuration in 2-inch inside-diameter by 3½-inch glass reactor. (Data from reference 58.)

The effect of pressure on the quenching distances or electrode spacings of various electrode configurations producing incendiary sparks is shown in figures 36 and 37. For constant spark-ignition energies, the quenching distances, or electrode spacings, of incendiary-spark-producing electrode configurations increase with decreasing inflammable mixture pressures. This phenomenon is explained by assuming that a constant spark-ignition energy can initially ignite a constant mass of inflammable mixture. Thus, with decreasing mixture pressure, ignition of a larger volume of inflammable mixture occurs, and the electrode spacing must be increased to accommodate the increased mixture volume.

Variation of minimum spark-ignition energy with mixture pressure is expressed in figures 38 to 40. For constant electrode spacing, the minimum spark-ignition energy of a mixture increases with decreasing mixture pressure. The minimum spark-ignition energies of inflammable mixtures increase rapidly near the minimum ignition pressures of the mixtures (fig. 40).

Varying temperature.—Varying the temperature of inflammable mixtures from -50° to 300° F has a small effect on the minimum ignition pressures of the mixtures when ignition is initiated by high-energy capacitance sparks. As indicated in figure 41, the minimum ignition pressures of *n*-butane-air and isooctane-air mixtures decrease linearly with increasing mixture temperatures when ignition is effected by capacitance sparks having spark-ignition energies from 720 to 8640 millijoules. The minimum ignition pressures of *n*-butane-air and isooctane-air mixtures are approximately the same regardless of the spark-ignition energies at mixture temperatures of 300° F.

FIGURE 38.—Effect of pressure of 8.5 to 9.5 percent by volume mixture of methane and air at temperature of 77° F on minimum spark-ignition energy for one electrode configuration. (Data from reference 50.)

FIGURE 39.—Minimum spark-ignition energy of glass-flanged electrode configurations as functions of electrode spacing and pressure of 9.5 percent by volume mixture of methane and air at temperature of 77° F. (Data from reference 50.)

FIGURE 42.—Effect of diluent-gas addition on minimum spark-ignition energy and quenching distance of methane-oxygen-diluent-gas mixtures at temperature of 77° F and pressure of 1 atmosphere. (Data from reference 50.)

EFFECT OF DILUENTS

The presence of diluent gases in an inflammable mixture exerts a significant influence on its electric spark ignition. Like heated surface ignition, the spark-ignition energy required to ignite inflammable mixtures containing large percentages of diluents depends on the absorptive and conductive powers of the diluents and the proportion of inflammable gas to oxygen. Figure 42 indicates the effect of diluents on the minimum spark-ignition energies and quenching distances of methane-oxygen-diluent-gas mixtures. In figures 42 (a) and 42 (b), the relative effect of the diluent gases is the same. With the exception of the methane-oxygen-argon mixtures, the minimum ignition energies and quenching distances increase with increasing diffusivity of the oxygen-

FIGURE 43.—Effect of diluent-gas addition on minimum ignition pressures of n-butane-oxygen-diluent-gas mixtures. Method of ignition, bomb; electrode spacing, 0.110 inch; capacitance-spark ignition energy, 8640 millijoules; volume of metal bomb, 750 cubic centimeters; mixture temperature, 74° to 82° F. (Data from reference 58.)

FIGURE 44.—Limits of inflammability of gasoline vapor in various air-diluent-gas atmospheres. Automobile-exhaust-gas composition: nitrogen, 85 percent by volume; carbon dioxide, 15 percent by volume. Gasolines tested: 73, 92, and 100 octane. Inflammable area covers entire area inside largest curve. (Data from reference 61.)

diluent-gas mixtures. This mixture diffusivity is expressed by

$$\alpha = \frac{k}{\rho c_p} \quad (6)$$

where

c_p mixture specific heat

k mixture thermal conductivity

α mixture thermal diffusivity

ρ mixture density

The minimum ignition pressures of mixtures of *n*-butane and oxygen, with argon, nitrogen, carbon dioxide, and helium as diluents are shown in figure 43. For all the inflammable mixtures containing diluents, the mixtures most and least ignitable are those containing argon and carbon dioxide, respectively. The effect of several diluents on the limits of inflammability of individual mixtures of 73-, 92-, and 100-octane gasoline and air is shown to be identical in figure 44. The lower limit of inflammability of the mixture is relatively unaffected, whereas the upper limit decreases approximately linearly with increasing amounts of diluents such as carbon dioxide, automobile exhaust gas, and nitrogen. Mixtures of 100-octane gasoline and air are rendered noninflammable by the addition of approximately 28.7, 36.0, and 42.5 percent by volume of carbon dioxide, automobile exhaust gas, or nitrogen, respectively. Halogenated hydrocarbons are more effective than any of these diluents in rendering gasoline-air mixtures noninflammable.

III—IGNITION BY FLAMES OR HOT GASES

Data pertaining to the ignition of inflammable mixtures by flames or hot gases are not extensive. Much of the available data pertain to the ignition of gas-air mixtures containing methane as the chief inflammable constituent. Whether the inflammable mixtures will or will not be ignited by flames or hot gases depends on mixture composition, duration of contact of the mixture with the ignition source, temperature of the ignition source, and size of the ignition source, in much the same manner as ignition by heated surfaces.

EFFECT OF VARYING MIXTURE COMPOSITION

The effect of mixture composition on the limiting diameters of openings for downward propagation of flames in methane-air mixtures is shown in figure 45. Limiting diameters occur with approximately stoichiometric compositions. The ignition of an inflammable mixture by a flame can be considered practically instantaneous. Methane-air mixtures exposed to flames 0.394, 0.492, and 0.591 inch in length exhibited ignition lags of 0.0068, 0.0042, and 0.0035 second, respectively; therefore, even though the ignition lag is practically zero for flame ignition, the lag decreases with increasing size of the ignition source. Minimum ignition lags have been found to occur with approximately stoichiometric mixtures.

LIMITING SIZE OF OPENINGS FOR FLAME PROPAGATION

The minimum quenching distances or the limiting diameters of tubes or holes in thin plates through which a flame will not propagate are expressed in figures 45 to 47. Minimum limiting tube and thin plate opening diameters of approximately 0.071 and 0.136 to 0.150 inch occurred for approximately stoichiometric mixtures of coal gas and methane with air, respectively. These limiting diameters for the downward propagation of flame in inflammable mixtures were determined for copper tubes having length-diameter ratios l/d of 10, and for circular openings in thin copper foil and mica plates having thicknesses of 0.0033 inch and 0.0024 to 0.0087 inch, respectively.

Some references (for example, references 62 and 67) indicate that the quenching of the flame is due solely to the

FIGURE 45.—Effect of mixture composition on limiting diameters of openings in copper and mica plates and copper tubes for downward flame propagation in methane-air mixtures at atmospheric pressure. (Data from reference 62.)

cooling effect of the unburned gases rather than a cooling effect due to varying thermal conductivity of the confining material. Data from reference 68 indicate that in addition to this effect the confining material and opening configuration may affect the quenching distance by varying the size of the dead space between the surface of the flame and the opening of the enclosure. The reduced inflammability range and the increased limiting diameter of opening for downward flame propagation determined with copper tubes instead of openings in copper foil may be due to an increase in the size of the dead space caused by the greater over-all cooling effect of the copper tubes. Investigations conducted with the glass tubes and the mica plates (references 62 and 63) gave approximately the same results as experiments in which copper tubes and plates were used.

No data were found in the survey of the literature to indicate the limiting sizes of openings for propagation of flames of gasoline-air mixtures. Reference 65, however, indicates that the quenching of laminar oxyhydrogen flames by solid surfaces is partly dependent on the factor k/SC , where

C heat capacity per unit volume of unburned mixture at quenching temperature

k thermal conductivity of unburned mixture at quenching temperature

S burning velocity of mixture

FIGURE 46.—Limiting diameters of circular openings and limiting distances between plates for downward propagation of flame in various vapor-air mixtures at atmospheric pressure.

FIGURE 47.—Quenching of propane-air flames at various mixture pressures and temperature of 75° F; downward flame propagation. (Data from reference 66.)

FIGURE 48.—Quenching of propane-air flames at various mixture pressures and temperature of 75° F. Downward-flame-propagation data, reference 66; spark-ignition data, reference 48.

Figure 46 was plotted, using values of k/SC calculated as indicated by reference 65. Experimental data, which pertain to the limiting size of openings for flame propagation in gasoline-air mixtures, are unavailable in the literature. Accordingly, k/SC was calculated for a stoichiometric n -octane-air mixture, which was assumed to be approximately the same as a stoichiometric gasoline-air mixture. This calculated value of k/SC indicates (fig. 46) that the limiting diameter of circular openings and the limiting distance between parallel plates for downward flame propagation in gasoline-air mixtures are approximately 0.13 and 0.09 inch, respectively.

EFFECT OF GAS PRESSURES AND TEMPERATURES

The effect of mixture pressure on the quenching of propane-air flames is indicated in figure 47. The configuration used consisted of a rectangular opening in $\frac{3}{16}$ -inch copper plates. The length-width ratio of the slit was always greater than 3.6. For all mixture pressures from 0.0832 to 2.77 atmospheres, the minimum limiting slit width for downward propagation of flame occurs with mixtures slightly richer than stoichiometric. As shown by figure 48, for any single mixture composition, the dependency of the limiting slit width on the mixture pressure is expressed approximately

by an equation of the form

$$w = Kp^n \quad (7)$$

FIGURE 49.—Quenching of propane-air flames at various mixture temperatures (gas and plates at same temperature). Pressure, 14.3 pounds per square inch absolute; slit length-width ratio, > 3.6; slit jaws, $\frac{3}{16}$ -inch copper plates; downward flame propagation. (Data from reference 66.)

where

K constant

n negative exponent

p mixture pressure

w slit width

The results of investigations conducted with propane-air flames at atmospheric pressure to determine the effect of mixture temperature on the limiting slit width of the quenching configuration just described are presented in figure 49. The mixture and the plates forming the rectangular opening were at the same temperature. For all temperatures from 80° to 545° F, the minimum limiting slit width occurs with mixtures slightly richer than stoichiometric. The limiting slit width decreases with increasing mixture temperature. Similar data for brass-plate protective devices in natural-

FIGURE 50.—Effect of plate temperature on performance of brass-plate protective device (plates, 0.09 in. by 4 in.) in inflammable atmospheres containing 8.6 to 9.5 percent by volume natural gas in air. (Data from reference 69.)

gas-air atmospheres are given in figure 50. The limiting distance between plates for a single mixture decreases linearly with increasing plate temperature.

EFFECT OF DILUENTS

The effect of diluents on the limiting diameter of openings for propagation of flames in methane-oxygen-nitrogen (air) and methane-oxygen-argon mixtures is shown in figure 51. The minimum limiting diameters of copper tubes (length-diameter ratio=10.0) are 0.150 and 0.087 inch, respectively, for flame propagation in the methane-air and methane-oxygen-argon mixtures. The cooling effect of the unburned gases is indicated by the smaller limiting diameters of openings for flame propagation in mixtures having the smaller heat capacities and thermal conductivities.

IV—RELATION OF PUBLISHED DATA TO AIRCRAFT-FIRE PROBLEMS

Fires in aircraft usually result from the ignition of inflammable vapors by heated surfaces, hot (electric) sparks and arcs, and flames or hot gases. The source of ignition can often be definitely determined for fires during flight or ground operation of aircraft, but the ignition source in crashes is often unknown, because the inflammables may sometimes be exposed to all the ignition sources simultaneously.

FIGURE 51.—Effect of diluent-gas additions on limiting diameters of openings for flame propagation in methane-oxygen-diluent-gas mixtures. Downward flame propagation through copper tubes; length-diameter ratio, 10.0; ratio of oxygen to diluent, 21:79. (Data from reference 63).

IGNITION BY HEATED SURFACES

Heated surfaces are common ignition hazards in aircraft environments. According to reference 70, hot exhaust ducts, combustion heaters, carburetor-air heaters, overheated cabin superchargers, moving parts overheated by friction, and short circuited or malfunctioning electric equipment have been responsible for the heated surface ignition of fires in airline aircraft in the decade prior to 1947. Of these surface-ignition hazards, the exhaust system is a continuous hazard during operation of the aircraft. The other ignition sources exist intermittently, generally because of malfunctioning or mechanical failure of the particular component.

A survey of air-transport crash records (reference 71) indicates that the inflammable most frequently initially involved in flight or ground fires and thus considered most hazardous of the liquids carried in aircraft is gasoline. Lubricating oil is not quite as hazardous as gasoline because of its much higher flash point and much lower volatility. Half the fires mentioned in the survey of flight fires involved either gasoline or lubricating oil as the initial inflammable.

In order to ignite any inflammable by a heated surface, the right proportions of the inflammable must contact the heated element. The temperature at which ignition occurs depends on the length of time the inflammable is in contact with the heated air or surface. According to the aforementioned survey, this contact is brought about during ground operation mainly by failure of the fuel plumbing system. Typical of fuel-plumbing-system failures are primer line failures, primer leaks, leaky hose connections, fuel pump leakage, and failure of the carburetor vent line. Serious accessory section fires in radial engines are often due to this type of failure, which allows inflammable vapors or fluids to escape and contact or drop on the hot exhaust stacks.

Flight fires are due primarily to engine failures, which usually are the result of structural faults of various components. Engine failures, especially in radial engines, often result in a rupture of the engine induction and exhaust systems. This type of failure can easily be brought about by engine cylinders displaced by broken connecting rods. When

FIGURE 52.—Zones of inflammability of fuel in aircraft fuel tanks. (Data from reference 72.)

FIGURE 52.—Zones of inflammability of fuel in aircraft fuel tanks. (Data from reference 72.)

FIGURE 53.—Variation of inflammability of kerosene and two engine oils of similar viscosity but different composition with altitude and temperature. (Data from reference 72.)

such a displacement occurs, inflammable fuel-air mixtures and hot lubricating oil are exposed to hot surfaces, which are primarily components of the exhaust system. Usually, it is difficult to state whether inflammation results from ignition of the gasoline or the lubricating oil. Crash fires are generally due to structural failure of the engine, but are much more severe than flight fires in most cases.

In the range of its ignition temperatures (450° to 1325° F), gasoline can exist only in the vapor state. Any mixture

capable of flame propagation must lie within the limits of inflammability. According to figure 52, aircraft fuel-tank minimum temperatures of -44° and 108° F are explosively dangerous at sea level for 100-octane aviation gasoline and kerosene, respectively. The area marked "equilibrium conditions" indicates the limiting conditions at which inflammable mixtures exist in the fuel tank in equilibrium with the fuel. Breathing, which widens the limiting conditions for gasoline, is the influx of air into a fuel tank during a descent

due to increasing atmospheric pressure. For kerosene, which has a flash point generally greater than ambient temperatures, the ignition zone is widened by conditions under which an ignitable spray may be formed. Research carried out since the publication of figure 52 (b) has shown that the zone in which spray ignition of kerosene may occur is known to be larger than reference 72 indicates. A fuel mist or spray may be formed by the rupture of a fuel tank by a missile or the rupture of a high pressure fuel line such as are present in turbojet engines. Similar data are plotted in figure 53 for kerosene and for two lubricating oils of different composition but of the same viscosity.

In any occurrence of these fire hazards in aircraft, the ignition temperature and ignitibility of the fuel or lubricating oil will be determined by conditions described in the detailed discussion presented herein. The values of ignition temperature and ignitibility defined by these conditions serve as approximate indications of the relative temperatures at which heated surfaces become practical hazards in aircraft environments. Reference 12 indicates that aviation gasoline will not ignite in air when exposed to the outer surfaces of exhaust pipes at temperatures below 850° F. Injected into air inside hot exhaust pipes, aviation gasoline ignited at duct temperatures as low as 536° F. Lubricating oil on the outer surfaces of exhaust ducts ignited at a minimum duct temperature of 625° F. Thus, for complete immunity to fires ignited by the components of the exhaust system, the surface temperatures should not be greater than approximately 500° F. Although existing knowledge does not permit a complete description of the components of the exhaust system that serve as ignition sources, it is presumed in this discussion that the exhaust duct, the exhaust valves, and the cylinder interiors are the active components.

Volatile fuels necessary for engine operation under a variety of climatic conditions may be responsible for the relative ignition hazard of present-day grades of gasoline used in aircraft operation. As the volatility of a fuel increases, the range in which ignition sources are hazardous increases. Fuels of low volatility would result in more difficult starting of aircraft engines, but would seemingly reduce the ignition hazard of fuel in aircraft environments.

Reduction of the fire hazard of the exhaust system can be accomplished by:

- (1) Keeping the inflammables from the hot surfaces
- (2) Releasing some substance into and around the exhaust system in order to prevent ignition if a crash is imminent
- (3) Cooling the exhaust system below temperatures capable of ignition of gasoline or oil
- (4) Increasing the minimum ignition temperature of the fuel or oil by changing the fuel or oil composition or by change of material used in the construction of the exhaust ducts
- (5) Changing the volatility of the fuel.

An extinguishing system capable of spraying or flooding the exhaust ducts would aid in preventing combustion by simultaneously blanketing and lowering the temperature of the heated surfaces. According to reference 73, "it is most important that the extinguishant should be actually injected into enclosed hot spaces such as exhaust ducts, long exhaust

pipes or collector rings, turbine compartments and tailpipe ducts, and combination heater chambers."

The ignition temperature of gasoline is increased by the addition of small amounts of tetraethyl lead, benzene, and similar substances. Possibly other substances can be found that will increase the ignition temperature without reducing the performance of the fuel in the engine.

Changes in the surface composition of the exhaust-duct material may effectively increase the ignition temperature of the fuel. Dependent upon the mixture composition, highly catalytic surfaces such as platinum must be heated to temperatures 300° to 700° F greater than stainless steel to ignite inflammable mixtures. Use of platinum is obviated by its cost and therefore the aforementioned comments are only of academic interest.

Fuel-volatility changes apparently are desirable relative to the fire-hazard problem. According to tables III and IV, the surface-ignition temperatures of low-volatility safety fuels do not vary greatly from those of regular grades of aviation gasoline. Reduced fuel volatility would not increase the ignition temperature of the fuel, but would reduce the volume in which an ignition source is hazardous.

IGNITION BY ELECTRIC SPARKS AND ARCS

Sparks resulting from short circuits in wiring or from failures of starters, magnetos, or generators; sparks from the continued functioning of nonflameproofed electric apparatus; sparks from the continued rotation of damaged parts; discharges from the brushes of rotating equipment; sparks from ground friction; electrostatic sparks; and electric arcs created by the separation of metallic contacting portions of the electric circuit such as voltage regulators may all be regarded as potential spark-ignition hazards in aircraft.

Flight fires in transport aircraft are initiated with equal frequency by either electric sparks or the exhaust ducts (reference 71). The damage incurred by the electric spark-ignited fires, however, was generally confined to the electric insulation. In addition, reference 74 shows that self-clearing arcs are statistically more prevalent during the breaking of a load-carrying circuit. The clearing time was from 0.05 to 2.5 seconds, with a median value of 0.6 second. Compared with the exhaust system, electric sparks are relatively short, minor ignition hazards during flight operation.

High-energy concentrations at short-circuited points result in self-clearing faults, but are generally accompanied by a scattering of molten metal globules over a considerable area. Low-energy concentrations at short-circuited points may result in a permanent welded contact between the conductor and the airplane structure. Self-clearing faults are probably more dangerous than welded faults because they are accompanied by extremely high temperatures and considerable arcing. Welded faults, however, may disrupt the entire electric system and thus interfere with control of the airplane.

Continued rotation of generators is generally not significant in propeller-type aircraft in the event of crash. In jet-type aircraft, free running turbines may, however, continue rotation of such parts.

According to the survey (reference 71) of fires in transport aircraft, two of the 61 crash fires reported were initiated by

sliding friction. Inasmuch as data indicate that friction sparks ordinarily lack the thermal energy capable of igniting inflammable mixtures, the source of ignition of these two crash fires may have been surfaces heated to high temperatures by sliding friction rather than by friction sparks.

Electrostatic sparks generated in aircraft environments may be ignition hazards. Electrostatic charges having potentials of 50 to 2000 volts have been accumulated in air of 30- to 51-percent humidity at atmospheric pressure and temperature by benzene flowing through a 0.12-inch tube into an insulated receiver. The following table from reference 75 indicates the potentials of electrostatic charges accumulated in air of 63-percent humidity at atmospheric conditions by benzene flowing through tubes of different materials.

Tube material	Potential of accumulated charge (volts)
Iron	4000
Brass	3600
Aluminum	2900
Copper	2030

In air of 78-percent humidity, no charge was accumulated when the benzene flowed under its own pressure, but even a slight increase in the liquid pressure resulted in an accumulation of a high-potential electrostatic charge. At liquid pressures of 2 to 6 atmospheres, electrostatic charges having potentials of 4000 volts and greater were accumulated. Thus, unless the equipment is suitably grounded, practically any transfer of fuel in any environment is hazardous.

According to reference 76, the potential of the electrostatic charge accumulated during fuel transference is approximately the same for any grade of gasoline or kerosene, increases with the length of time of the transferring operation, increases with increasing fuel velocity, and is relatively unaffected by atmospheric conditions except that it decreases with increasing humidity of the air.

The capacitance of the human body has been determined (reference 77) as 0.0001 to 0.0004 microfarad. Values of 0.00028 to 0.00032 microfarad were consistently obtained for the capacitance of a person leaning against a wall. An individual charged to a potential of 10,000 volts would have an electrostatic spark energy of 15 millijoules. Because many inflammable mixtures have minimum spark-ignition energies less than 15 millijoules, and this amount of electrostatic spark energy is easily acquired by ungrounded personnel, equipment, and wiring, grounding precautions should be taken.

Most of the sparks occurring in aircraft environments ordinarily contain many times the energy required to ignite inflammable mixtures. Sparks of this type must be prevented from occurring in an inflammable atmosphere. According to reference 73, crash switches that cut off or isolate all electric equipment are a possibility. Batteries can no longer be regarded as the only power source in crashed airplanes. Although the generators in airplanes powered by reciprocating engines would be stopped during a crash by propeller stoppage, free-running turbines of jet-engine air-

craft may necessitate de-energizing fields or short circuiting the generator across its terminals if it would aid in stopping the turbine. Isolation of the electric system can stop electric fuel pumps and close solenoid valves supplying fuel to combustion heaters.

Short-circuit faults in aircraft can probably be protected by rapid acting selective fuses or circuit breakers that would isolate the fault from the rest of the circuit. In general, fuses are less desirable than circuit breakers because of their time-operating characteristics and the fact that they must be replaced after one operation. As indicated by reference 74, the isolating action must be very quick because the circuit voltage drops rapidly in the faulted circuit. This drop in voltage could cripple the entire electric system of the aircraft by allowing relays and contactors to open because of low voltage on the closing coils.

Improved design of the load-carrying cables might result in reduction of the spark-ignition hazard. This improvement might be accomplished by using a conduit containing the electric leads embedded in a solid insulating material. Another possibility in the design of the electric circuits is the inclusion of mechanically weak spots surrounded by inert materials such as powders. During crashes, cable separation would occur at the weak points with the energy released by any sparks being dissipated in inert atmospheres.

IGNITION BY FLAMES OR HOT GASES

Exposure of inflammable vapors to flames or hot gases constitutes the third important fire hazard in aircraft environments. Large, disastrous fires may result from the exposure of inflammable mixtures to exhaust flames and gases or flames initiated by electric spark or heated surface-ignition sources. Possible reduction of these ignition hazards seems more difficult than the reduction of spark or heated surface hazards. Use of the cooled exhaust gases to inert engine nacelles and fuel-tank compartments would prevent contact between inflammable mixtures and hot exhaust gases or flames during flight or ground operation. Simultaneously, the exhaust gases would be inerting hazardous portions of the plane. During a crash, however, such inerting may be ineffective. A possible solution to the problem of flames or hot gases during crashes may be quick acting, crash-actuated mechanisms capable of flooding the engine and exhaust system with fire extinguishing agents.

CONCLUSIONS

An analysis of the available literature included in the survey resulted in the following conclusions:

The inflammability ranges of most hydrocarbon-air mixtures decreased with decreasing mixture pressures and temperatures. The minimum spark-ignition energies of inflammable mixtures and the quenching distances of electrode configurations both increased with decreasing mixture pressures. As a result of these effects, sea-level pressures and temperatures of inflammable mixtures were the most critical design considerations, relative to the reduction of fire hazards in aircraft environments.

Generally, the ignition temperatures of hydrocarbons in air increased with different variables as shown in the following table:

Decreasing variable	Increasing variable
Ignition lag Igniting surface area Fuel quality or cetane number Boiling point or number of carbon atoms in n-paraffins	Mixture turbulence Mixture velocity Surface catalytic activity Tetraethyl lead additions

Ignition temperatures of hydrocarbons were also increased if scale or ash existed on the igniting surfaces or if the inflammables were dropped on heated surfaces in the open air. The ignition temperatures of hydrocarbons containing the same number of carbon atoms were lowest for normal paraffins followed by paraffinic isomers and aromatics.

Gasoline exhibited zones of ignition and nonignition for certain oxygen-fuel ratios much in the same manner as normal octane. The ignition temperature of gasoline in air depends on the degree of confinement of the mixture by the experimental apparatus. Dependent on the experimental conditions and the degree of confinement, the ignition temperatures of gasoline in air may range from 450° to 1325° F. The lower and upper limits of inflammability of 100-octane gasoline in air at atmospheric conditions were approximately 1.40 percent and 7.40 percent by volume, respectively, and the minimum ignition pressure was approximately 35 millimeters of mercury absolute. The minimum diameter of a hole or tube through which a gasoline-air mixture flame would not propagate downwards was approximately 0.13 inch as determined from interpolation of data of known mixtures.

Minimum spark-ignition energies of inflammable mixtures were greatly dependent upon the electrode configurations; these energies increased with increasing size of electrodes and mixture velocity and decreased with increasing electrode spacings. Minimum spark-ignition energies as low as 0.28 millijoule were capable of ignition of methane-air mixtures. Electrode material had no visible effect on mixture ignition by capacitance sparks, but the minimum ignition energies of inductance sparks decreased with decreasing electrode-material density. The measured minimum ignition energies of inductance sparks decreased with increasing spark potentials, and were unaffected by alternating or direct currents. Although high humidity content of the air tends to prevent accumulations of electrostatic charges capable of producing sparks having sufficient energy to ignite vapor-air mixtures, practically any transfer of fuel in any environment was hazardous unless the equipment was suitably grounded.

An increase in the amount of diluent gases in a mixture increased the ignition temperature. In hydrocarbon-oxygen-diluent-gas mixtures containing either argon, carbon dioxide, helium or nitrogen as the diluent component, lowest values of quenching distances, minimum ignition energies, and minimum ignition pressures were exhibited with inflammable mixtures containing argon as the diluent gas. Highest values of quenching distances and minimum ignition energies were exhibited with inflammable mixtures containing helium as the diluent gas; highest values of minimum ignition pressures

were exhibited with inflammable mixtures containing carbon dioxide as the diluent. In order to render any mixture of 100-octane gasoline and air noninflammable, approximately 42.5, 36.0, and 28.7 percent by volume of nitrogen, automobile exhaust gas, or carbon dioxide, respectively, were necessary.

Application of the survey data to the aircraft-fire problem indicated the possibility of reducing aircraft-fire hazards by means of the following remedial measures:

- (1) Prevention of contact of fuels or fuel vapors with the hot exhaust surfaces
- (2) Release of an extinguishing agent inside of and around the exhaust system if a crash is imminent
- (3) Reduction of the temperature of the exhaust duct or gases below the surface-ignition temperature of gasoline and lubricating oil in the event of a crash
- (4) Increase of the surface-ignition temperatures of gasoline and lubricating oil
- (5) Use of fuels of reduced volatility
- (6) Elimination of the electrical generating system as an ignition hazard in the event of a crash
- (7) Inerting of engine nacelles and wing compartments.

TABLE I—SURFACE IGNITION TEMPERATURES OF SEVERAL INFLAMMABLES IN AIR

(a) Ignition surfaces, heated 6-inch-diameter steel tube and open steel plate (reference 72)

Fuel	Ignition temperature (°F)		Flash point (°F)
	Tube (a)	Plate	
Gasoline (unleaded).....	473	>1238	-44
100-Octane aviation gasoline (leaded).....	734	>1238	-44
Kerosene.....	417	1202	108
Hydraulic fluid.....	455	752	302
Lubricating oil.....	572	806	482

(a) Heated-surface ignition environments.

(b) Ignition surfaces, heated nickel or iron plates (reference 24)

Plate, 0.5 or 1.0 mm by 45 mm by 140 mm; temperatures measured by iron-constantan thermocouple soldered to plate.]

Fuel	Surface ignition temperature (°F)
Benzene.....	1400
Toluene.....	1409
Ethyl alcohol.....	1274
Cyclohexane.....	1125
n-Pentane.....	1085
n-Heptane.....	1058
n-Decane.....	1085
Rumanian aviation gasoline.....	1085
Shale-oil gasoline.....	1040
Green mineral oil.....	977
Dimethylcyclohexene.....	833

TABLE II—EFFECT OF IGNITION-SURFACE COMPOSITION ON SURFACE IGNITION TEMPERATURES OF SEVERAL FUELS IGNITED IN AIR BY STATIC CRUCIBLE METHOD

(a) Data from reference 40

[All configurations are 106-cc cylinders except pyrex surface, which is 125-cc spherica configuration.]

Fuel	Surface ignition temperature (°F)			
	Pyrex	Copper	Low-carbon steel	Chromium
n-Hexane.....	479	510	516	513
n-Heptane.....	452	481	484	483
Isobutyl alcohol.....	825	861	902	862
Gasoline (Socony).....	497	534	550	559

(b) Data from reference 36

[Ignition volume, 1180 cc; ignition lag, 1 sec.]

Fuel	Surface ignition temperature (°F)	
	Platinum	Pyrex
n-Pentane (technical grade).....	1074	1009
n-Hexane.....	968	959
n-Octane.....	856	815
Isooctane.....	1042	999
Isododecane.....	993	930
Benzene.....	1213	1144
Toluene.....	1171	1119
Mesitylene.....	1150	1110
p-Xylene.....	1144	1103
Methyl alcohol.....	1065	997
Ethyl alcohol (abs.).....	1035	1011
n-Propyl alcohol.....	1004	979
Benzyl alcohol.....	936	829
Isopropyl alcohol.....	1148	990
Isobutyl alcohol.....	1008	972
Isoamyl alcohol.....	964	840
Ethylene glycol.....	972	855

TABLE III—EFFECT OF OCTANE NUMBER ON SURFACE IGNITION TEMPERATURE OF UNLEADED LIQUID FUELS IGNITED IN AIR BY DYNAMIC CRUCIBLE METHOD OF IGNITION (REFERENCE 78)

Fuel	Octane number	Surface ignition temperature (°F) (*)	Flash point (°F)	A.S.T.M. distillation (°F)			Reid vapor pressure (lb at 100° F)	
				Initial boiling point	Percentage evaporated			
					10	50		90
Certified 2,2,4-trimethylpentane.....	100	970		211	211	211	1.5

REPORT 1020

MEASUREMENTS OF AVERAGE HEAT-TRANSFER AND FRICTION COEFFICIENTS FOR SUBSONIC FLOW OF AIR IN SMOOTH TUBES AT HIGH SURFACE AND FLUID TEMPERATURES¹

By LEROY V. HUMBLE, WARREN H. LOWDERMILK, and LELAND G. DESMON

SUMMARY

An investigation of forced-convection heat transfer and associated pressure drops was conducted with air flowing through smooth tubes for an over-all range of surface temperature from 535° to 3050° R, inlet-air temperature from 535° to 1500° R, Reynolds number up to 500,000, exit Mach number up to 1, heat flux up to 150,000 Btu per hour per square foot, length-diameter ratio from 30 to 120, and three entrance configurations. Most of the data are for heat addition to the air; a few results are included for cooling of the air. The over-all range of surface-to-air temperature ratio was from 0.46 to 3.5.

Correlation of the measured average heat-transfer and friction coefficients with heat addition by conventional methods wherein the physical properties of the air were evaluated at the average air temperature resulted in considerable decreases in both the Nusselt number and the friction coefficient at constant Reynolds number in the turbulent region, as the ratio of surface temperature to air temperature was increased. The effect of surface-to-air temperature ratio was eliminated by evaluating the physical properties of air, including density, in the Reynolds number, the Nusselt number, and the friction coefficient at a temperature higher than the average air temperature.

Correlation of the heat-transfer coefficients was also affected by increases in the average air temperature, produced by increasing the inlet-air temperature, which resulted in a decrease in the Nusselt number. This effect of temperature level was reduced by using the smallest variation of thermal conductivity with temperature available in the literature and was eliminated when the thermal conductivity was arbitrarily assumed to vary as the square root of temperature.

INTRODUCTION

A large amount of data is available in the literature on forced-convection heat transfer from surfaces to fluids. Most of these data, however, have been obtained at relatively low surface temperatures and heat-flux densities, and do not extend into the range of high temperature and flux that is of interest in many current engineering applications. Inasmuch as convective heat transfer is a boundary-layer phenomenon, the severe temperature and velocity gradients

in the fluid film adjacent to the surface (and attendant variation in fluid properties), which accompany heat transfer at high flux densities, make extrapolation of existing data for low flux densities uncertain. This possibility has been previously recognized; for example, in references 1 and 2 it is indicated that heat transfer and friction may depend on both surface and fluid temperatures.

An experimental investigation was undertaken at the NACA Lewis laboratory during 1948-50 to obtain heat-transfer and related pressure-drop information for a wide range of surface and fluid temperatures and heat flux. As part of the general program, an investigation was made with air flowing through smooth tubes. The effects of such variables as surface temperature, inlet-air temperature, and tube-entrance configuration on heat transfer and pressure drop have been investigated and are reported in references 3 to 6. The results of references 3 to 6 are summarized herein and, in addition, previously unpublished data showing the effect of tube length-diameter ratio and inlet-air temperature on heat-transfer and friction coefficients at high surface temperature and heat flux are presented. Most of the data are for heat addition to the air; however, a few previously unpublished results are included for heat extraction from the air.

APPARATUS

ARRANGEMENT

A schematic diagram of the equipment used in the investigation is shown in figure 1 (a). Compressed air was supplied through a pressure-regulating valve, cleaner, and surge tank to a second pressure-regulating valve where the flow rate was controlled. From this second valve, the air flowed through metering devices and a preheater into a mixing tank, which consisted of three concentric passages so arranged that the air made three passes through the tank before entering the test section. Baffles were provided in the central passage to insure thorough mixing of the air before it entered the test section. From the test section the air flowed through a second mixing tank and was discharged to the atmosphere. The test section, mixing tanks, and adjoining piping were thermally insulated.

Desmon and Eldon W. Sams, 1950.

(a) Schematic diagram of setup.

(b) Typical test section showing thermocouple and pressure-tap locations.

FIGURE 1.—Arrangement of apparatus for heating air.

The temperature of the air entering and leaving the test section was measured by thermocouples located downstream of the mixing baffles in the entrance and exit mixing tanks, respectively.

For the runs with heat addition to the air, electric power was supplied to the test section from a 208-volt, 60-cycle supply line through an autotransformer and a step-down power transformer. The low-voltage leads from the power transformer were connected to flanges on the test section by flexible copper cables. A voltmeter, an ammeter, and a wattmeter were provided to measure the electric-power input to the test section.

For the runs with heat extraction from the air, the electric-power supply was disconnected and the test section was surrounded with a water jacket. The warmed air from the preheater was cooled in the water-jacketed test section.

TEST SECTIONS

Most of the investigation was conducted using test sections fabricated from commercial Inconel tubing. The range of tube-wall temperature was extended beyond that attainable with Inconel by using one test section made of platinum (reference 6), which was installed in a separate setup similar to that shown in figure 1 (a). One of the test sections used

(a) Long approach.
(b) Right-angle edge.
(c) Bellmouth.

FIGURE 2.—Entrances to test sections.

for heating the air is illustrated schematically in figure 1 (b). Flanges were attached to both ends of the tube to provide electric contact with the power supply. The dimensions of the various tubes used as test sections in the investigation were as follows:

Tube material	Inside diameter (in.)	Outside diameter (in.)	Heat-transfer length (in.)	Length-diameter ratio
Inconel.....	0.402	0.500	12	30
Do.....	.402	.500	24	60
Do.....	.402	.500	48	120
Platinum.....	.525	.685	24	46

Outside-wall temperatures were measured at a number of stations along the tube by means of thermocouples and self-balancing indicating-type potentiometers. Chromel-alumel thermocouples were used with the Inconel test sections, and platinum-platinum-rhodium thermocouples, with the platinum test section. In general, at each station along the tube, two thermocouples were located diametrically opposite and

the average of the two temperatures was taken as the outside-wall temperature at the station. Static-pressure taps were located at intervals along each of the Inconel test sections.

Investigations were made with heat addition to the air using three types of entrance on the 24-inch Inconel tube (reference 5). The entrances, shown in figure 2, were (a) long approach, (b) right-angle edge, and (c) bellmouth.

The cooling data were obtained with an Inconel test section having a length-diameter ratio of 60 and a bellmouth entrance.

PROCEDURE

The following general procedure was used in obtaining the experimental data: For the heating runs, the inlet-air temperature was set at the desired value, the inlet-air pressure was adjusted to give the minimum desired flow rate (minimum Reynolds number), and the electric-power input was adjusted to give the desired tube-wall temperature. After equilibrium conditions had been attained, electric-power input, flow rate, temperatures, and pressures were recorded. The air flow and the power input were then increased in increments (to increase the Reynolds number while maintaining constant wall temperature) and data were recorded after each incremental increase. The foregoing procedure was repeated for a range of tube-wall temperature with each of the various test sections and entrance configurations.

For the cooling runs, the inlet-air pressure was adjusted to give the minimum desired air-flow rate at the desired inlet-air temperature. The water-flow rate in the water jacket was set at a constant value. After equilibrium conditions were obtained, the data were recorded as in the heating runs. The inlet-air pressure was then incrementally varied to cover a range of Reynolds number while maintaining constant inlet-air temperature. The foregoing procedure was repeated for a range of inlet-air temperature.

The over-all range of conditions for which data were obtained is summarized in the following table:

Reference	Tube material	Length-diameter ratio	Entrance type	Maximum bulk Reynolds number	Average tube-wall temperature (°R)	Inlet-air temperature (°R)	Maximum exit Mach number
3	Inconel	60	Bellmouth	250,000	680-1700	535	1.0
4	do.	60	do.	500,000	535-2050	535	1.0
5	do.	60	Long approach, right angle	375,000	535-1960	535	1.0
6	Platinum	46	Long approach, right angle	320,000	980-3050	535-1160	0.6
(a)	Inconel	30	Bellmouth	390,000	535-1685	535	1.0
(a)	do.	120	do.	282,000	535-1850	535-1400	1.0
(a), (b)	do.	60	do.	250,000	535-585	535-1500	1.0

* Previously unpublished.
 b Cooling data.

The over-all range of heat-flux density encountered in the investigation was from 500 to 150,000 Btu per hour per square foot of heat-transfer area.

SYMBOLS

The following symbols are used in the report:

c_p	specific heat of air at constant pressure (Btu/(lb) (°F))
D	inside diameter of test section (ft)
f	average friction coefficient
f_f, f_s	modified average friction coefficient
G	mass velocity (mass flow per unit cross-sectional area) (lb/(hr) (sq ft))
g	acceleration due to gravity (4.17×10^8 ft/hr ²)
h	average heat-transfer coefficient (Btu/(hr) (sq ft) (°F))
k	thermal conductivity of air (Btu/(hr) (sq ft) (°F/ft))
k_t	thermal conductivity of test-section material (Btu/(hr) (sq ft) (°F/ft))
L	heat-transfer length of test section (ft)
P	absolute total or stagnation pressure (lb/(sq ft))
p	absolute static pressure (lb/(sq ft))
Δp	over-all static-pressure drop across test section (lb/(sq ft))
Δp_f	friction static-pressure drop across test section (lb/(sq ft))
Q	rate of heat transfer to air (Btu/hr)
R	gas constant for air (53.35 ft-lb/(lb) (°F))
r	radius of test section (ft)
S	heat-transfer area of test section (sq ft)
T	total or stagnation temperature (°R)
T_b	average bulk temperature, defined by $(T_1 + T_2)/2$, (°R)
T_f	average film temperature, defined by $(T_s + T_b)/2$, (°R)
$T_{0.75}$	average film temperature, defined by $T_b + 0.75(T_s - T_b)$, (°R)
T_o	average outside-wall temperature of test section (°R)
T_s	average inside-wall (surface) temperature of test section (°R)
t	static temperature (°R)
V	velocity (ft/hr)
V_{av}	average velocity, defined by G/ρ_{av} , (ft/hr)
W	air flow (lb/hr)
x	distance from entrance of test section (ft)
γ	ratio of specific heats of air
μ	absolute viscosity of air (lb/(hr) (ft))
ρ	density of air (lb/(cu ft))
ρ_{av}	average density of air defined by $(p_1 + p_2)/R(t_1 + t_2)$, (lb/(cu ft))
$c_p \mu / k$	Prandtl number
GD/μ	Reynolds number
$\rho_f V_b D / \mu_f$	modified Reynolds number
$\rho_{0.75} V_b D / \mu_{0.75}$	
$\rho_s V_b D / \mu_s$	
hD/k	Nusselt number

Subscripts:

1	test-section entrance
2	test-section exit
<i>i</i>	inner surface of test section
<i>o</i>	outer surface of test section
<i>b</i>	bulk (when applied to properties, indicates evaluation at average bulk temperature T_b)
<i>f</i>	film (when applied to properties, indicates evaluation at average film temperature T_f)
0.75	film (when applied to properties, indicates evaluation at $T_{0.75}$)
<i>s</i>	surface (when applied to properties, indicates evaluation at average inside-wall temperature of test section T_s)

METHOD OF CALCULATION

Physical properties of air.—The physical properties of air used in the present investigation are shown in figure 3 as functions of temperature. The solid curves are from references 7 and 8, and are in agreement with the values of reference 9. The dashed curve for thermal conductivity is from reference 10. The dotted curve represents values of thermal conductivity assumed herein to vary as the square root of temperature and its use will be discussed in a subsequent section. The thermal conductivities from references 7 to 10 were

FIGURE 3.—Variation of thermal conductivity, absolute viscosity, specific heat, and Prandtl number of air with temperature.

extrapolated considerably beyond the range of experimental data in the reference reports and have been extrapolated still further in figure 3 to cover the temperature range of the present investigation. The upper temperature limits of the experimental data upon which values of thermal conductivity from references 7, 8, and 10 are based are 1050°, 1360°, and 1215° R, respectively.

Except where otherwise stated, the physical property data of references 7 and 8 are used in the present report.

Determination of surface temperature.—The average outside-wall temperature of the test section T_o was obtained by measuring the area under a curve of the temperature distribution (as obtained from thermocouple readings) along the heat-transfer length and dividing the area by this length.

For the heating runs, the average inside-wall (surface) temperature T_s was then calculated by the following equation (derived in reference 11):

$$T_s = T_o - \frac{Q}{2\pi L k_i (r_o^2 - r_i^2)} \left(r_o^2 \ln \frac{r_o}{r_i} - \frac{r_o^2 - r_i^2}{2} \right) \quad (1)$$

In equation (1), the assumptions are made that heat is generated uniformly across the tube-wall thickness and that the heat flow from every point in the tube material is radially inward. For the present investigation, the radial temperature drop through the tube wall, calculated from equation (1), was very small compared with the difference between the average inside-wall and the air bulk temperature.

For the cooling runs, the thermocouples were imbedded in the test-section wall and were assumed to measure the inside-wall temperature, inasmuch as the calculated temperature drops through the wall were small.

Heat-transfer coefficients.—The average heat-transfer coefficient h was computed from the experimental data by the relation

$$h = \frac{W c_{p,a} (T_2 - T_1)}{S (T_s - T_b)} \quad (2)$$

The use of the total air temperature T_b instead of adiabatic wall temperature was considered justified because the difference between these temperatures was small compared with the difference between the average surface and air (or adiabatic wall) temperatures.

Correlation of the average heat-transfer coefficients with the pertinent variables is discussed in the section **RESULTS AND DISCUSSION**.

Friction coefficients.—Friction data were obtained with and without heat transfer. Average friction coefficients were calculated from the experimental pressure-drop data as follows: The friction pressure drop was obtained by subtracting the calculated momentum pressure drop from the measured static-pressure drop across the test section. Thus

$$\Delta p_{fr} = \Delta p - \frac{G}{g} (V_2 - V_1) = \Delta p - \frac{G^2 R}{g} \left(\frac{t_2}{p_2} - \frac{t_1}{p_1} \right) \quad (3)$$

where t_1 and t_2 , the absolute static temperatures at entrance and exit of the test section, respectively, were, in general, calculated from the measured values of air flow, static pressure, and total temperature by the following equation, which is obtained by combining the perfect gas law, the equation of continuity, and the energy equation:

$$t = -\frac{\gamma g}{(\gamma-1)R} \left(\frac{p}{G}\right)^2 + \sqrt{\left[\frac{\gamma g}{(\gamma-1)R} \left(\frac{p}{G}\right)^2\right]^2 + 2T \frac{\gamma g}{(\gamma-1)R} \left(\frac{p}{G}\right)^2} \quad (4)$$

For the bellmouth entrance, it was found that the entrance static temperature t_1 could be represented with sufficient accuracy by the relation

$$t_1 = T_1 \left(\frac{p_1}{P_1}\right)^{\frac{\gamma-1}{\gamma}} \quad (5)$$

In equation (5) the total pressure at the test-section entrance P_1 was assumed to be equal to the static pressure in the entrance mixing tank, where the velocity was negligible.

Average friction coefficients were calculated by dividing the friction pressure drop by four times the length-diameter ratio of the tube times a dynamic pressure. The density in the dynamic pressure was computed in three ways, resulting in three definitions of friction coefficient.

The first of these friction coefficients was based on a density evaluated at the average static pressure and temperature of the air in the tube; thus

$$f = \frac{\Delta p_{fr}}{4 \frac{L}{D} \frac{\rho_{av} V_{av}^2}{2g}} = \frac{g \rho_{av} \Delta p_{fr}}{2 \frac{L}{D} G^2} \quad (6)$$

where

$$\rho_{av} = \frac{1}{R} \left(\frac{p_1 + p_2}{t_1 + t_2}\right) \quad (7)$$

In the other two definitions of friction coefficient, the density was evaluated at the film temperature T_f and at the average surface temperature T_s , resulting in equations (8) and (9), respectively:

$$f_f = \frac{\Delta p_{fr}}{4 \frac{L}{D} \frac{\rho_f V_{av}^2}{2g}} = \left(\frac{\rho_{av}}{\rho_f}\right) f = \left(\frac{2T_f}{t_1 + t_2}\right) f \quad (8)$$

$$f_s = \frac{\Delta p_{fr}}{4 \frac{L}{D} \frac{\rho_s V_{av}^2}{2g}} = \left(\frac{\rho_{av}}{\rho_s}\right) f = \left(\frac{2T_s}{t_1 + t_2}\right) f \quad (9)$$

Correlation of the friction data is discussed in the following section.

RESULTS AND DISCUSSION

AXIAL WALL-TEMPERATURE DISTRIBUTIONS

Representative axial wall-temperature distributions obtained with heat addition to the air in an Inconel tube having a length-diameter ratio of 60 and a bellmouth entrance

are shown in figure 4. The outside-wall temperature is plotted against the ratio of the distance from the tube entrance to the heat-transfer length x/L for five different rates of heat transfer to the air. The rate of heat transfer to the air, the air flow, the average inside tube-wall temperature, and the temperature rise of the air are tabulated.

The wall temperature increases almost linearly over the major portion of the tube length, and the slope of this part of the curve increases with an increase in rate of heat input. The large axial-temperature gradients at the entrance and exit of the test section are the result of conduction losses through the electric connector flanges and cables.

The curves in figure 4 are typical; similar trends were obtained with other entrances and for other length-diameter ratios.

FIGURE 4.—Representative outside-wall temperature distribution for various amounts of heat input to air. Reynolds number, approximately 140,000; Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R.

CORRELATION OF HEAT-TRANSFER COEFFICIENTS

Conventional correlation based on average air temperature.—Forced-convection, turbulent-flow, heat-transfer coefficients are generally correlated with other pertinent variables by means of the familiar relation in which Nusselt number divided by Prandtl number to a power (generally 0.4) $\frac{hD}{k} / \left(\frac{c_p \mu}{k}\right)^{0.4}$ is plotted against Reynolds number GD/μ , and in which the physical properties of the fluid (specific heat, viscosity, and thermal conductivity) are usually eval-

uated at the average fluid temperature. Results obtained by heating air flowing through an Inconel tube having a length-diameter ratio of 60 and a bellmouth entrance (reference 4) are plotted in this manner in figure 5 (a). The data shown are for an inlet-air total temperature of 535° R and cover a range of Reynolds number from about 7000 to 500,000. Included for comparison is the average line obtained by McAdams (reference 2) from correlation of the results of various investigators. The equation corresponding to this reference line is

$$\frac{hD}{k_b} = 0.023 \left(\frac{GD}{\mu_b} \right)^{0.8} \left(\frac{c_{p,b} \mu_b}{k_b} \right)^{0.4} \quad (10)$$

(a) Physical properties of air evaluated at average bulk temperature.

(b) Physical properties of air evaluated at average surface temperature.

FIGURE 5.—Conventional methods of correlating heat-transfer coefficients. Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R.

A family of parallel lines representing the various surface-to-air temperature ratios and having slopes of about 0.8 at Reynolds numbers above approximately 25,000 is obtained.

The data for low surface temperatures (T_s , 605° R) are in reasonable agreement with the reference line; however, as the surface temperature is raised the data fall progressively below the reference line. For example, at a Reynolds number of 70,000, an increase in T_s/T_b from 1.1 to 2.5 (corresponding to an increase in surface temperature from 605° to 2050° R) results in a decrease in the ordinate parameter of about 38 percent. Inasmuch as the corresponding change in Prandtl number to the 0.4 power is small, about the same percentage decrease occurs in Nusselt number.

The results shown in figure 5 (a) are typical of those obtained with other entrance configurations and length-diameter ratios.

Conventional correlation based on surface temperature.—

The heat-transfer data of figure 5 (a) are replotted in figure 5(b), wherein the physical properties of the air are evaluated at the average inside-wall temperature T_s . The line representing equation (10), but with the physical properties evaluated at T_s , is included for comparison. The data again show a separation with surface temperature level, which in this case is greater than when the properties are evaluated at the bulk temperature. The use of any temperature between these extremes would, of course, cause an intermediate amount of separation of the data.

In references 1 and 12, heat-transfer coefficients were predicted for fully developed flow of fluids having a Prandtl number of 1.0 in smooth tubes. The analyses took into consideration the radial variation of fluid properties and indicated an effect of surface-to-fluid temperature ratio analogous to that shown in figure 5.

Effect of surface-to-fluid temperature ratio.—The magnitude of the effect on the heat-transfer correlations of surface-to-fluid temperature ratios greater than 1.0 is illustrated more clearly in figure 6. Lines are shown for which the air properties are evaluated at bulk temperature T_b , film temperature T_f , and surface temperature T_s . The lines corresponding to evaluation of properties at T_b and T_s are cross plots of the data at a Reynolds number of 100,000 from figures 5 (a) and 5 (b), respectively. The line corresponding to evaluation of air properties at T_f was obtained from a plot similar to those of figure 5.

A series of straight lines is obtained, which intersect at T_s/T_b of 1.0, at which point the ordinate parameter has the value predicted by equation (10). The lines have increasingly greater negative slopes as the temperature at which the fluid properties are evaluated is increased. For example, an increase in T_s/T_b from 1.0 to 2.5 results in a decrease in the ordinate parameter of about 40 percent when the properties are evaluated at T_b , of 48 percent when evaluated at T_f , and of 54 percent when evaluated at T_s .

Appreciable error can be made (fig. 6) if conventional heat-transfer correlation equations are used to compute heat-transfer coefficients for surface-to-fluid temperature ratios appreciably greater than 1.0.

Modified correlation based on surface temperature.—

The slope of the line in figure 6 corresponding to evaluation of the fluid properties at T_s is -0.8 . The ordinate in this case is $(hD/k_s)/(c_{p,s}\mu_s/k_s)^{0.4}$ and the corresponding Reynolds number is defined by GD/μ_s . Inasmuch as at $T_s/T_b=1.0$ equation (10) applies, it might be expected that the effect of T_s/T_b could be eliminated by incorporating the term $(T_b/T_s)^{0.8}$ in equation (10) with the properties evaluated at T_s . Thus

$$\frac{hD}{k_s} = 0.023 \left(\frac{GD}{\mu_s} \right)^{0.8} \left(\frac{T_b}{T_s} \right)^{0.8} \left(\frac{c_{p,s}\mu_s}{k_s} \right)^{0.4} \quad (11)$$

If the difference between total and static temperatures is neglected,

$$\frac{T_b}{T_s} = \frac{\rho_s}{\rho_b} \quad (12)$$

and the following relation is obtained by letting $G = \rho_b V_b$:

$$\left(\frac{GD}{\mu_s} \right) \left(\frac{T_b}{T_s} \right) = \frac{\rho_s V_b D}{\mu_s} \quad (13)$$

Equation (13) defines a modified form of Reynolds number in which the conventional mass velocity G is replaced by the product of air density evaluated at the average surface temperature ρ_s and air velocity evaluated at the average bulk temperature V_b . Substituting equation (13) in equation (11) gives

$$\frac{hD}{k_s} = 0.023 \left(\frac{\rho_s V_b D}{\mu_s} \right)^{0.8} \left(\frac{c_{p,s}\mu_s}{k_s} \right)^{0.4} \quad (14)$$

The data of figure 5 are replotted in figure 7. Nusselt

FIGURE 6.—Variation of Nusselt number divided by Prandtl number to 0.4 power with ratio of surface-to-bulk temperature using conventional methods of correlating heat-transfer coefficients. Reynolds number, 100,000; Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R.

number divided by Prandtl number to the 0.4 power is plotted against the modified Reynolds number $\rho_s V_b D / \mu_s$.

The use of the modified Reynolds number eliminates the trends with respect to surface-to-bulk temperature ratio, so that for the range of surface temperature and Reynolds number shown the data can be represented with good accuracy by a single line. For modified Reynolds numbers above about 10,000, the data can be represented very well by equation (14).

Effect of entrance configuration.—Heating data obtained with an Inconel tube having a length-diameter ratio of 60 and both long-approach and right-angle-edge entrances are shown in figure 8. The coordinates are the same as in figure 7, and the line representing the data of figure 7 (bellmouth entrance) is included in the figure.

FIGURE 7.—Modified method of correlating heat-transfer coefficients. Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R; physical properties of air evaluated at surface temperature.

The long-approach and bellmouth entrances tend to provide fully developed and uniform velocity profiles, respectively, at the inlet to the test section. The right-angle-edge entrance is typical of most tube-type heat exchangers.

As shown in figure 8, the data obtained with the long-approach and right-angle-edge entrances can be represented with good accuracy by the line which best fitted the data for the bellmouth entrance shown in figure 7. It may be concluded that the average heat-transfer coefficient is negligibly affected by the entrance configurations investigated, at least for length-diameter ratios of the order of 60 or greater.

Effect of length-diameter ratio.—Heating data obtained with Inconel tubes having length-diameter ratios of 30 and 120 and with a platinum tube having a length-diameter ratio of 46 (reference 6) are shown in figure 9 (a). The coordinates are the same as in figures 7 and 8 and the line (shown solid) representing the data of figures 7 and 8, which

are for a length-diameter ratio of 60, is included. The Inconel tubes had bellmouth entrances, and the platinum tube had a long-approach entrance; however, as indicated in figure 8, the effect of entrance configuration is negligible.

A small trend with respect to length-diameter ratio is evident in the turbulent region. The data for length-diameter ratios less than 60 tend to fall parallel to, but above, the reference line, whereas the data for a length-diameter ratio of 120 fall below the line. This effect of length-

FIGURE 8.—Effect of entrance configuration using modified method of correlating heat-transfer coefficients. Inconel tube; length-diameter ratio, 60; inlet-air temperature, 535° R; physical properties of air evaluated at surface temperature.

diameter ratio has been observed by other investigators (see, for example, references 1 and 13) and was accounted for by including a power function of the length-diameter ratio in the general correlation equation. The exponent 0.054 is quoted in reference 1 and the value 0.1 is quoted in reference 13. The exponent 0.1 applies best for the present data and accordingly the data of figures 7 and 9 (a), corrected for the effect of length-diameter ratio, are replotted in figure 9 (b).

The correction for length-diameter ratio appreciably improves the correlation for modified Reynolds numbers above approximately 10,000, and in this region the data can be represented by the following equation:

$$\frac{hD}{k_s} = 0.034 \left(\frac{\rho_s V_b D}{\mu_s} \right)^{0.8} \left(\frac{c_{p,s} \mu_s}{k_s} \right)^{0.4} \left(\frac{L}{D} \right)^{-0.1} \quad (15)$$

The constant 0.034 is 0.023 (equation (14)) multiplied by $60^{0.1}$, where 60 is the length-diameter ratio of the tube used in obtaining the data upon which equation (14) is based.

The data for modified Reynolds numbers below about 10,000 show a trend with respect to length-diameter ratio and cannot be represented by a single line.

FIGURE 9.—Effect of ratio of length to diameter using modified method of correlating heat-transfer coefficients. Inconel and platinum tubes; inlet-air temperature, 535° R; physical properties of air evaluated at surface temperature.

The data shown in figure 9 for the platinum tube (L/D , 46) were obtained for surface temperatures up to 3050° R and surface-to-air temperature ratios up to 3.5; it is of interest that, for this extended range of temperature, the data are correlated with negligible scatter by use of the modified Reynolds number.

Effect of air temperature.—The data presented thus far were obtained with an inlet-air temperature of about 535° R. A wide range of surface temperature and corresponding surface-to-air temperature ratio was investigated. In order to determine whether the correlation applied for a wider

range of air temperature, tests were made in which the inlet-air temperature, and hence average air temperature, was varied. The results are shown in figure 10.

Inspection of figure 10 indicates that the ordinate parameter decreases as the inlet-air temperature and the corresponding average air temperature increase. For example, in figure 10 (a), at a Reynolds number of approximately 100,000 and a surface temperature of approximately 1800° R, an increase in inlet-air temperature from 535° to 1460° R (with a corresponding decrease in T_s/T_b from 1.9 to 1.2) results in a reduction in the ordinate parameter of about 24 percent. The ordinate parameter would decrease further if the inlet temperature were increased until T_s/T_b was approximately 1.0. At constant values of T_s/T_b , the ordinate parameter varies approximately as temperature to the -0.2 power.

As much as one-fourth of the observed separation of the data with temperature level may be caused by experimental error in measuring air temperature at the high temperature levels. Inasmuch as there is a considerable variation in the reported values of thermal conductivity at high temperature, as is evident in figure 3, the effect may be partly or entirely the result of using improperly extrapolated values of thermal conductivity.

The values of conductivity from references 7 and 8, which have been used thus far in correlating the present data, vary approximately as the 0.85 power of the absolute temperature. The values from reference 10 vary approximately as the 0.73 power of the temperature. Inasmuch as the ordinate parameter of figure 10 varies inversely as conductivity to the 0.6 power, the conductivity would have to vary as temperature to the 0.85 power minus 0.2 divided by 0.6, or to the 0.5 power, in order to completely eliminate the effect of temperature level in figures 10 (a) and (b).

Inspection of figures 5 and 6 indicates that the use of smaller values of thermal conductivity at high temperatures in correlation of the data would also result in a decrease of the effect of surface-to-air temperature ratio, so that correlation of the data according to equation (15), in which the fluid physical properties and density are evaluated at the surface temperature, would result in an overcorrection of the data with increasing values of surface-to-air temperature ratio. A relation of the form of equation (15) can, however, be used for correlation of the data by evaluating the fluid physical properties and density at a reference temperature lower than the surface temperature. For example, if conductivity is assumed to vary as temperature to the 0.73 power, the effect of surface-to-air temperature ratio can be decreased by using a reference temperature $T_{0.75}$ midway between T_f and T_s . If conductivity is assumed to vary as the square root of temperature, the effect can be eliminated by using the film temperature T_f as the reference temperature.

In order to illustrate the effect of using smaller values of thermal conductivity at high temperatures, the data of

(a) Physical properties of air evaluated at surface temperature; thermal conductivity proportional to $T^{0.85}$; Inconel tube; length-diameter ratio, 120.

(b) Physical properties of air evaluated at surface temperature; thermal conductivity proportional to $T^{0.85}$; platinum tube; length-diameter ratio, 46.

FIGURE 10.—Effect of inlet-air temperature using modified method of correlating heat-transfer coefficients.

figure 10 (a) are replotted in figure 10 (c) using the conductivity data of reference 10, and with the physical properties and density evaluated at the film temperature $T_{0.75}$. The line representing equation (15), which for the lower reference temperature becomes

$$\frac{hD}{k_{0.75}} = 0.034 \left(\frac{\rho_{0.75} V_b D}{\mu_{0.75}} \right)^{0.8} \left(\frac{c_{p,0.75} \mu_{0.75}}{k_{0.75}} \right)^{0.4} \left(\frac{L}{D} \right)^{-0.1} \quad (15a)$$

is included for comparison.

(c) Physical properties of air evaluated at film temperature $T_{b,75}$; thermal conductivity proportional to $T^{0.75}$; Inconel tube.

(d) Physical properties of air evaluated at film temperature T_f ; thermal conductivity proportional to $\sqrt{T}$; Inconel tube.

FIGURE 10.—Concluded. Effect of inlet-air temperature using modified method of correlating heat-transfer coefficients.

For an inlet-air temperature of 1460° R, a surface temperature of 1850° R, and a Reynolds number of 85,000, the ordinate parameter is about 15 percent below the reference line. Comparison of figures 10 (a) and 10 (c) indicates that the use of the lower values of conductivity from reference 10 reduces the effect of temperature level by approximately one-half, or for constant values of T_s/T_b , the ordinate parameter varies as temperature to the -0.1 power.

The data of figure 10 (b), although not shown, would fall within the total separation of the data in figure 10 (c).

Figure 10 (d) is included to illustrate the effect of using still lower values of thermal conductivity at high temperatures. The data are the same as in figures 10 (a) and 10 (c), but in figure 10 (d) the conductivity is assumed to vary as the square root of temperature and the physical properties and density are evaluated at the film temperature T_f . The line representing equation (15), which for the reference film temperature T_f becomes

$$\frac{hD}{k_f} = 0.034 \left(\frac{\rho_f V_b D}{\mu_f} \right)^{0.8} \left(\frac{c_{p,f} \mu_f}{k_f} \right)^{0.4} \left(\frac{L}{D} \right)^{-0.1} \quad (15b)$$

is included for comparison.

In figure 10 (d) it is indicated that both the effects of air temperature and surface-to-air temperature ratio are eliminated by use of the assumed conductivity-temperature relation and by evaluation of the physical properties and density at the film temperature. The data can be represented with good accuracy by equation (15b).

No justification of the arbitrarily assumed conductivity-temperature relation shown in figure 3 can be given other than that it results in the best correlation of the data reported herein.

Effect of heat extraction.—In reference 12, it is predicted that with heat extraction from the air the Nusselt number would increase as the heat-flux density increases, or as the surface-to-air temperature ratio decreases. It was further found that the effect could be eliminated by evaluating the physical properties and density at a reference temperature midway between T_b and T_s .

Tests were conducted to determine whether or not the effect of T_s/T_b on correlation of heat-transfer coefficients was the same for heat extraction as for heat addition. These results were obtained with an Inconel tube having a length-diameter ratio of 60 and a bellmouth entrance for a range of T_s/T_b from 0.46 to 0.82. The data are correlated in the conventional manner in figure 11 using thermal conductivities from references 7 and 8 with the physical properties evaluated at the average temperature T_b . Included is the line representing equation (10) modified for variation in L/D , which becomes

$$\frac{hD}{k_b} = 0.034 \left(\frac{GD}{\mu_b} \right)^{0.8} \left(\frac{c_{p,b} \mu_b}{k_b} \right)^{0.4} \left(\frac{L}{D} \right)^{-0.1} \quad (16)$$

The effect of a decrease in T_s/T_b from 0.82 to 0.46 on the correlation of the data is negligible, and the data can be adequately represented by equation (16).

The data in figure 11 do not necessarily show that no effect of T_s/T_b exists for cooling inasmuch as the use of a smaller variation of conductivity with temperature would result in an increase in Nusselt number for a decrease in T_s/T_b and hence introduce an effect of T_s/T_b into the data.

FIGURE 11.—Conventional method of correlating heat-transfer coefficients with heat extraction from air. Inconel tube; length-diameter ratio, 60; bellmouth entrance.

The effects of using smaller variations of conductivity are shown in figures 12 (a) and 12 (b) with the data based on the conductivity data of reference 10 and on the assumption that conductivity varies as the square root of temperature, respectively. In figure 12 (a), the data are correlated according to equation (15a) for heat addition. A considerable overcorrection for the effects of T_s/T_b is obtained, which indicates that the effect of T_s/T_b for cooling is smaller than that obtained for heating. In figure 12 (b), however, where the data are correlated according to equation (15b) for heat addition, the separation of the data is very small, indicating that for the assumption that conductivity varies as the square root of temperature the effect of T_s/T_b is the same for both the heating and cooling data, and that both the cooling and the heating data can be represented by equation (15b).

Summary plots of heat-transfer data.—Heat-transfer data have been shown for a range of Reynolds number, surface temperature, inlet-air temperature, entrance configuration, and length-diameter ratio, and for heating and cooling of the air. The results are summarized in figure 13, which shows on single plots data from previous figures, which include all the foregoing variables.

The data are correlated in figure 13 (a) by the modified method using the thermal conductivity data of references 7 and 8 with the physical properties and density evaluated at T_s . The line representing equation (15) is included for comparison. As previously shown, all the heating data obtained with an inlet-air temperature of 535° R regardless of length-diameter ratio, surface temperature, or entrance configuration can be represented with good accuracy by the

(a) Physical properties of air evaluated at film temperature $T_{0.75}$; thermal conductivity proportional to $T_{0.75}$.

(b) Physical properties of air evaluated at film temperature T_f ; thermal conductivity proportional to $\sqrt{T}$.

FIGURE 12.—Modified method of correlating heat-transfer coefficients with heat extraction from air.

reference line. The high inlet-air temperature data and the cooling data fall below the reference line, so that equation (15) does not apply with desirable accuracy for all the conditions investigated.

The data of figure 13 (a) are replotted in figure 13 (b) using the thermal conductivity data from reference 10, and with the physical properties and density evaluated at $T_{0.75}$.

(a) Physical properties of air evaluated at surface temperature T_s ; thermal conductivity proportional to $T_s^{0.85}$.

(b) Physical properties of air evaluated at film temperature $T_{0.75}$; thermal conductivity proportional to $T_{0.75}^{0.73}$.

FIGURE 13.—Summary plot of experimental data using modified method of correlating heat-transfer coefficients.

The line representing equation (15a) is included. Trends with temperature level and with T_s/T_b are reduced compared with figure 13 (a). The high inlet-air temperature data and the cooling data again deviate farthest from the reference line.

(c) Physical properties of air evaluated at film temperature T_f ; thermal conductivity proportional to $\sqrt{T}$.

FIGURE 13.—Concluded. Summary plot of experimental data using modified method of correlating heat-transfer coefficients.

Figure 13 (c) shows the data of figures 13 (a) and 13 (b) replotted using the assumption that thermal conductivity varies as the square root of temperature, and with the physical properties and density evaluated at T_f . The line representing equation (15b) is included. The conductivity-temperature relation assumed in figure 13 (c) results in the best correlation of all the present data. Trends with respect to temperature level and with T_s/T_b for both heat addition and heat extraction are almost completely eliminated and the data can be represented by equation (15b).

CORRELATION OF FRICTION COEFFICIENTS

Friction coefficients without heat transfer.—Average half-friction coefficients $f/2$ calculated by equation (6) for flow without heat transfer are plotted against Reynolds number GD/μ_b in figure 14 (a). Included for comparison is the line representing the Kármán-Nikuradse relation between friction coefficient and Reynolds number for incompressible turbulent flow, which is

$$\frac{1}{\sqrt{8 \frac{f}{2}}} = 2 \log \left(\frac{GD}{\mu_b} \sqrt{8 \frac{f}{2}} \right) - 0.8 \quad (17)$$

and the line representing the equation for laminar flow in circular tubes, which is

$$\frac{f}{2} = \frac{8}{GD \mu_b} \quad (18)$$

Reasonably good agreement with the Kármán-Nikuradse line is obtained for all five configurations in the range of Reynolds number corresponding to turbulent flow. It is of interest that the Kármán-Nikuradse relation, which was derived for incompressible flow, applies with good accuracy to compressible flow, inasmuch as the present data cover a range of tube-exit Mach number up to 1.0.

Figure 14 (a) illustrates the agreement of the data obtained in the present investigation without heat transfer with the results of other investigators, which are in general agreement with equations (17) and (18).

Friction coefficients with heat addition.—Representative friction data, obtained with heat addition to the air, are shown in figure 14 (b). Data for no heat transfer (T_s/T_b , 1.0), and the Kármán-Nikuradse and laminar flow lines are included for comparison. These data are for an Inconel tube having a length-diameter ratio of 60 and a bellmouth entrance, and were obtained simultaneously with the heat-transfer data of figure 5.

The data for low surface temperatures (T_s , 605° and 675° R) agree fairly well with those for no heat addition. As the surface temperature is increased, however, $f/2$ decreases at high Reynolds numbers and stays the same or increases at

(a) No heat transfer; Inconel tubes; inlet-air temperature, 535° R.
(b) Heat addition; Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R.

FIGURE 14.—Variation of average half-friction coefficient with Reynolds number.

(a) Viscosity and density evaluated at surface temperature T_s .

FIGURE 15.—Variation of modified half-friction coefficient with modified Reynolds number with heat addition. Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R.

low Reynolds numbers, so that the data cannot be represented by a single line. These results are typical of those obtained with other entrances and length-diameter ratios.

Modified friction coefficient.—Various methods of defining the Reynolds number and the dynamic pressure on which to base the average friction coefficient were tried in an attempt to eliminate the trends shown in figure 14 (b). One such method was to base the dynamic pressure on a density evaluated at the surface temperature and a velocity evaluated at the average air temperature and to plot the resulting friction coefficient against the modified Reynolds number $\rho_s V_b D / \mu_s$. The friction coefficient defined in the foregoing way f_s is given by equation (9).

The results of this method of correlating the friction data are illustrated in figure 15 (a), where $f_s/2$ is plotted against $\rho_s V_b D / \mu_s$. The data are the same as in figure 14 (b), and curves representing the Kármán-Nikuradse and the laminar flow equations are again included.

In general, the friction coefficient is overcorrected and increases with an increase in T_s/T_b at constant modified Reynolds number. Figure 15 (a) is typical of the results obtained with other entrances and length-diameter ratios.

The friction factor was also defined on the basis of a density evaluated at the film temperature T_f (equation (8)). The resulting friction coefficient was then plotted against the modified Reynolds number with the density and viscosity evaluated at the film temperature T_f . The data of figure 15 (a) are replotted in this manner in figure 15 (b). The trends with T_s/T_b are eliminated for Reynolds numbers above 20,000 and the data can be represented with reasonable accuracy by the Kármán-Nikuradse relation using modified parameters.

Effect of entrance configuration.—Friction data obtained simultaneously with the heat-transfer data of figure 8 using an Inconel tube (length-diameter ratio, 60) with long-approach and right-angle-edge entrances are shown in figure 16 (a). Data for no heat transfer are included. At Reynolds numbers above 20,000, the data of figure 16 (a) are in reasonable agreement with the Kármán line, which was seen in figure 15 (b) to fit the bellmouth-entrance data with good accuracy. The data for the right-angle-edge entrance fall slightly below the reference line. No particular significance can be attached to this small deviation, however, and it is felt that the average friction coefficients for all three entrances can be approximated with sufficient accuracy at modified Reynolds numbers greater than about 20,000 by the relation

$$\frac{1}{\sqrt{8 \frac{f_f}{2}}} = 2 \log \left(\frac{\rho_f V_b D}{\mu_f} \sqrt{8 \frac{f_f}{2}} \right) - 0.8 \quad (19)$$

(b) Viscosity and density evaluated at film temperature T_f .

FIGURE 15.—Concluded. Variation of modified half-friction coefficient with modified Reynolds number with heat addition. Inconel tube; length-diameter ratio, 60; bellmouth entrance; inlet-air temperature, 535° R.

Effect of length-diameter ratio and inlet-air temperature.—Friction data obtained with heat addition to the air for length-diameter ratios of 30 and 120 and for inlet-air temperatures from 535° to 1460° R are shown in figure 16 (b). The data of figure 16 (b), which are for a bellmouth entrance, fall above the Kármán line, whereas the bellmouth data in figure 15 (b), which correspond to a length-diameter ratio of 60, fall on the line. No particular significance can be attached to these differences, however, and it is felt that the data for the range of length-diameter ratio and inlet-air temperature considered can be represented with sufficient accuracy by equation (19).

(a) Effect of entrance configuration with heat addition. Inconel tube; length-diameter ratio, 60; inlet-air temperature, 535° R.

(b) Effect of length-diameter ratio and inlet-air temperature with heat addition. Inconel tubes.

(c) Effect of heat extraction. Inconel tube; length-diameter ratio, 60.

FIGURE 16.—Variation of modified half-friction coefficient with modified Reynolds number.

Effect of heat extraction.—Friction coefficients obtained simultaneously with the data of figure 11 for heat extraction from the air are shown in figure 16 (c). Data for no heat transfer are included. The coordinates and the reference line are the same as in figures 15 (b) to 16 (b). The data can be represented with reasonable accuracy by the reference line for turbulent flow.

SUMMARY OF RESULTS

The results of this investigation of heat transfer and associated pressure drops conducted with air flowing through smooth tubes for a range of surface-to-air temperature ratio from 0.46 to 3.5, surface temperature from 535° to 3050° R, inlet-air temperature from 535° to 1500° R, Reynolds number up to 500,000, exit Mach number up to 1.0, length-diameter ratio from 30 to 120, and for three entrance configurations may be summarized as follows:

1. Conventional methods of correlating average heat-transfer coefficients, wherein specific heat, viscosity, and thermal conductivity are evaluated at the average air temperature, resulted in a considerable and progressive separation of the data with increased surface-to-air temperature ratio for heat addition to the air. Evaluation of the physical properties at the film or surface temperature, instead of the bulk temperature, aggravated the separation.

2. Satisfactory correlation of heating data obtained with inlet-air temperatures near 535° R was obtained for the range of surface temperature considered when the Reynolds number was modified by substituting the product of air density evaluated at the surface temperature and velocity evaluated at the average total air temperature for the conventional mass flow per unit cross-sectional area, and the properties of the air were evaluated at the average surface temperature.

3. Correlation of the heating data obtained at inlet-air temperatures above 535° R by the modified method resulted in a decrease in Nusselt number for an increase in average air temperature, which was eliminated by the assumption that the thermal conductivity of air varies as the square root of temperature and by the evaluation of the physical properties of air including density at a temperature midway between air and surface temperatures instead of at the surface temperature.

4. With the assumption that thermal conductivity varies as the square root of temperature, data obtained for cooling of the air indicated that the effect of surface-to-air temperature ratio was the same as for heat addition, so that both heating and cooling data can be represented by the same equation.

5. The use of different entrances to the test section (that is, a long-approach, a right-angle-edge, or a bellmouth entrance) had negligible effect on average heat-transfer coefficients, at least for length-diameter ratios of 60 or greater.

6. Variation in tube length-diameter ratio had a relatively small effect on average heat-transfer coefficients, which was satisfactorily accounted for by including a parameter for length-diameter ratio in the correlation equation.

7. Friction coefficients for no heat transfer, calculated from a dynamic pressure based on an average air density, were in good agreement with those obtained by other investigators. The corresponding friction coefficients obtained

with heat addition to the air showed a considerable effect of surface-to-air temperature ratio for the Reynolds numbers in the turbulent region.

8. All the friction data could be represented with reasonable accuracy by the Kármán-Nikuradse relation for incompressible turbulent flow by using a friction coefficient calculated from a dynamic pressure based on a density evaluated at the film temperature and the modified Reynolds number in which the density and viscosity were evaluated at a temperature midway between the air and surface temperatures.

REPORT 1021

ANALYSIS OF PLANE-PLASTIC-STRESS PROBLEMS WITH AXIAL SYMMETRY IN STRAIN-HARDENING RANGE¹

By M. H. LEE WU

SUMMARY

A simple method is developed for solving plane-plastic-stress problems with axial symmetry in the strain-hardening range which is based on the deformation theory of plasticity employing the finite-strain concept. The equations defining the problems are first reduced to two simultaneous nonlinear differential equations involving two dependent variables: (a) the octahedral shear strain, and (b) a parameter indicating the ratio of principal stresses. By multiplying the load and dividing the radius by an arbitrary constant, it is possible to solve these problems without iteration for any value of the modified load. The constant is determined by the boundary condition.

This method is applied to a circular membrane under pressure, a rotating disk without and with a central hole, and an infinite plate with a circular hole. Two materials, Inconel X and 16-25-6, the octahedral shear stress-strain relations of which do not follow the power law, are used. Distributions of octahedral shear strain, as well as of principal stresses and strains, are obtained. These results are compared with the results of the same problems in the elastic range. The variation of load with maximum octahedral shear strain of the member is also investigated.

The following conclusions can be drawn:

- 1. Inasmuch as the ratios of the principal stresses remain essentially constant during loading for the materials considered, the deformation theory is applicable to this group of problems.*
- 2. In plastic deformation, the distributions of the principal strains and of the octahedral shear strain are less uniform than in the elastic range, although the distributions of the principal stresses were more uniform. The stress-concentration factor around the hole is reduced with plastic deformation, but a high strain-concentration factor occurs.*
- 3. For the rotating disk and the infinite plate the deformation that can be sustained by the member before failure depends mainly on the maximum octahedral shear strain of the material.*
- 4. The added load that the member could sustain between the onset of yielding and failure depended mainly on the octahedral shear stress-strain relations of the material.*

INTRODUCTION

In the design of turbine rotors, it is desirable to know the detailed stress and strain distributions in the strain-hardening

range and the increase in load that can be sustained between the onset of yielding and failure. It is also desirable to know the effects of a notch or a hole in a turbine rotor or other machine members that are stressed in the strain-hardening range. If a member is thin, it can be analyzed on the basis of plane stress. For problems of this type for ideally plastic material, Nadai obtained solutions for a thin plate with a hole and a flat ring radially stressed (reference 1), and Nadai and Donnell obtained a solution for a rotating disk (reference 2). For materials having strain-hardening characteristics, a solution of plane-stress problems has been obtained by Gleyzal for a circular membrane under pressure (reference 3). The concept of infinitesimal strain was used and the solution was obtained by an iterative procedure with a good first approximate solution. The plastic laws were always satisfied by using a chart given in reference 3. In reference 4, a trial-and-error method is given for a rotating disk with very small plastic strain, in which the elastic stresses and strains are used as the first approximate values. An experimental investigation of high-speed rotating disks is given in reference 5; distributions of plastic strains (logarithmic strains) for different types of disk are measured. Reference 6 gives an experimental investigation of the burst characteristics of rotating disks; stress at the center of the disk is calculated by assuming that the material behaves elastically at the burst speed; the average tangential stress along the radius at burst speed is also calculated.

A simple method of solving plane-plastic-stress problems with axial symmetry in the strain-hardening range for finite strains was developed at the NACA Lewis laboratory during 1949-50. This method is based on the deformation theory of Hencky and Nadai (references 7 to 9), which is derived for the condition of constant directions and ratios of the principal stresses during loading. The equations of equilibrium, strain, and plastic law are reduced to two simultaneous nonlinear differential equations involving three variables, one independent and two dependent, that can be integrated numerically to any desired accuracy. These variables are the proportionate radial distance, the octahedral shear strain, and a parameter α that indicates the ratio of principal stresses. The magnitude of variation in calculated values of the parameter α with change in load directly indicates whether the deformation theory is applicable to the problem.

¹ Supersedes NACA TN 2217, "Analysis of Plane-Stress Problems With Axial Symmetry in Strain-Hardening Range" by M. H. Lee Wu, 1950.

The method developed is applied to: (1) a circular membrane under pressure, in order to compare results obtained by this method with those obtained by Gleyzal (reference 3); (2) rotating disks without and with a circular central hole, in order to investigate plastic deformation in such disks and the effects of the hole; and (3) an infinite plate with a circular hole or a flat ring radially stressed, in order to investigate the effects of the hole in the strain-hardening range.

In the investigation of (2) and (3), two materials, Inconel X and 16-25-6, with different strain-hardening characteristics were used in order to determine the effect of the octahedral shear stress-strain curve on plastic deformation. The octahedral shear stress of these two materials is not a power function of the octahedral shear strain, so that more general information can be obtained. Distributions of stresses and strains of the same problems in the elastic range are also calculated for purposes of comparison.

Acknowledgment is made to Professor D. C. Drucker for his discussion of this work and for his suggestion to examine whether the logarithmic strain could be applied correctly to the present problems and his suggestion to plot the stress-strain curves of Inconel X and 16-25-6 on a logarithmic scale in order to show that these materials do not obey the power law.

SYMBOLS

The following symbols are used in this report:

A, B, C, D, E, F	coefficients of nonlinear differential equations; functions of α, γ , and $\frac{r}{k}$
a	initial radius of hole
b	initial outside radius of membrane, rotating disk, or flat ring
c	initial outside radius of plate, very large compared with radius a
G, H, J, L	trigonometric functions of α
h	instantaneous thickness of membrane, rotating disk, or plate
h_{init}	initial thickness of membrane, disk, or plate
K_1, K_2	arbitrary loading constants
k	constant having a dimension of length
p	pressure on membrane
r	radial coordinate of undeformed membrane, disk, or plate
s	arc length
u	radial displacement
w	axial displacement
z	axial coordinate
α	parameter indicating ratio of principal stresses
γ	octahedral shear strain
ϵ	logarithmic strain (natural strain), logarithm of instantaneous length divided by initial length of element
θ	angular coordinate

ρ	mass per unit volume
σ	true normal stress, normal force per unit instantaneous area
τ	octahedral shear stress
ω	angular velocity
Subscripts:	
b	at radius b
c	at radius c
o	at center for member without hole; at radius a for member with concentric circular hole
1, 2, 3	principal directions in general
r, θ, z	principal directions: radial, tangential, and axial directions

STRESS-STRAIN RELATIONS IN PLASTIC DEFORMATION

The deformation theory of plasticity for ideally plastic materials was developed by Hencky from the theory of Saint Venant-Levy-Mises for the cases in which the directions and the ratios of principal stresses remain constant during loading (reference 7). Nadai extended the theory to include materials having strain-hardening characteristics (references 8 and 9). The conditions for the deformation theory have been emphasized by Nadai (reference 9, p. 209), Ilyushin (references 10 and 11), Prager (reference 12), and Drucker (reference 13). Experiments conducted by Davis (reference 14), Osgood (reference 15), and others on thin tubes subjected to combined loads with the directions and the ratios of the principal stresses constant throughout the tube and remaining constant during loading show that good results can be expected from the deformation theory.

In more recent experiments on thin tubes by Fraenkel (reference 16) and Davis and Parker (reference 17), it has been shown that even with considerable variation of the ratios of principal stresses during loading the strains obtained from the experiments were in good agreement with the strains predicted by use of the deformation theory. Further experimental investigation is needed to determine the extent to which the variation of ratios of principal stresses is permissible with the deformation theory. However, when the variation is small (approximately 10 percent over the strain-hardening range), the deformation theory can be expected to give good results.

In the present problems with axial symmetry, the directions of the axes of the principal stresses remain fixed during loading and it is probable that the ratios of principal strains and of principal stresses also remain approximately constant. The deformation theory previously discussed is therefore used. The stress-strain relations are as follows:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad (1)$$

$$\frac{\sigma_1 - \sigma_2}{\epsilon_1 - \epsilon_2} = \frac{\sigma_2 - \sigma_3}{\epsilon_2 - \epsilon_3} = \frac{\sigma_3 - \sigma_1}{\epsilon_3 - \epsilon_1} \quad (2)$$

$$\tau = \tau(\gamma) \quad (3)$$

where

$$\tau = \frac{1}{3} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \quad (4a)$$

$$\gamma = \frac{2}{3} [(\epsilon_1 - \epsilon_2)^2 + (\epsilon_2 - \epsilon_3)^2 + (\epsilon_3 - \epsilon_1)^2]^{1/2} \quad (4b)$$

From equations (1), (2), and (4a) or (4b), the following relations are obtained:

$$\epsilon_1 = \frac{1}{3} \frac{\gamma}{\tau} \left[\sigma_1 - \frac{1}{2} (\sigma_2 + \sigma_3) \right]$$

$$\epsilon_2 = \frac{1}{3} \frac{\gamma}{\tau} \left[\sigma_2 - \frac{1}{2} (\sigma_3 + \sigma_1) \right]$$

$$\epsilon_3 = \frac{1}{3} \frac{\gamma}{\tau} \left[\sigma_3 - \frac{1}{2} (\sigma_1 + \sigma_2) \right]$$

For plane-stress problems $\sigma_3 = 0$. It is convenient to use cylindrical coordinates for the problems considered; the principal directions 1, 2, and 3 in the preceding equations become radial, circumferential, and axial directions, respectively. The equations thus become

$$\epsilon_r + \epsilon_\theta + \epsilon_z = 0 \quad (1a)$$

$$\tau = \frac{\sqrt{2}}{3} (\sigma_r^2 - \sigma_r \sigma_\theta + \sigma_\theta^2)^{1/2} \quad (5a)$$

$$\gamma = 2 \sqrt{\frac{2}{3}} (\epsilon_r^2 + \epsilon_r \epsilon_\theta + \epsilon_\theta^2)^{1/2} \quad (5b)$$

and

$$\epsilon_r = \frac{1}{3} \frac{\gamma}{\tau} \left(\sigma_r - \frac{1}{2} \sigma_\theta \right) \quad (6a)$$

$$\epsilon_\theta = \frac{1}{3} \frac{\gamma}{\tau} \left(\sigma_\theta - \frac{1}{2} \sigma_r \right) \quad (6b)$$

$$\epsilon_z = \frac{1}{3} \frac{\gamma}{\tau} \left[-\frac{1}{2} (\sigma_r + \sigma_\theta) \right] = -(\epsilon_r + \epsilon_\theta) \quad (6c)$$

When σ_r and σ_θ are expressed in terms of ϵ_r and ϵ_θ , there is obtained

$$\left. \begin{aligned} \sigma_r &= 2 \frac{\tau}{\gamma} (2\epsilon_r + \epsilon_\theta) \\ \sigma_\theta &= 2 \frac{\tau}{\gamma} (2\epsilon_\theta + \epsilon_r) \end{aligned} \right\} \quad (7)$$

Because large deformations in the strain-hardening range will be considered, the concept that the change of dimension of an element is infinitesimal compared with the original dimension of the element is not accurate enough. Hence, the finite-strain concept, which considers the instantaneous dimension of the element, is used. (The equations of infinitesimal strains considered as special cases of finite strains are given in appendix A.) The stress is then equal

to the force divided by the instantaneous area and the strains are defined by the following equation:

$$\delta(\epsilon_j) = \frac{\delta(l_j)}{l_j}$$

where l_j is the instantaneous length of a small element having the original length of $(l_j)_0$ and j is any principal direction. During plastic deformation, the plastic strains at a particular state depend on the path by which that state is reached. For the paths along which the ratios of principal stresses remain constant during loading, however, the octahedral shear stress-strain relation, the value of the octahedral shear strain, and the values of the principal strains are defined by the initial and final states (references 14, 15, and reference 9, p. 209); $\delta(\epsilon_j)$ is then an exact differential and

$$\epsilon_j = \log_e \frac{l_j}{(l_j)_0} \text{ or } e^{\epsilon_j} = \frac{l_j}{(l_j)_0} \quad (8)$$

It should be noted that the condition under which equation (8) was obtained is also one of the conditions under which the deformation theory is derived; as long as the deformation theory is applicable, equation (8) can also be used.

EQUATIONS OF EQUILIBRIUM AND STRAINS INVOLVING DISPLACEMENTS CIRCULAR MEMBRANE UNDER PRESSURE

Equations of equilibrium and equations of strain are derived for a circular membrane under pressure. The membrane considered is so thin that bending stress can be neglected (reference 18, p. 576). Figure 1 shows the membrane clamped at the rim and subjected to a pressure p and

FIGURE 1.—Thin circular membrane (under pressure) and its element in deformed state.

a small element defined by $\Delta\theta$ and Δs taken at radius $r+u$ in the deformed state. In the undeformed state, the same element would be at radius r and defined by $\Delta\theta$ and Δr . The dotted lines represent an undeformed membrane. The instantaneous thickness of the element and the stresses acting on the element are also shown in the figure. Two principal stresses are σ_r and σ_θ , and ϕ is the angle between σ_r and the original radial direction.

Equations of equilibrium.—When all the forces acting on the element in the direction of σ_r are summed up, the following equation of equilibrium is obtained:

$$\sigma_r(r+u)h\Delta\theta - (\sigma_r + \Delta\sigma_r)[r+u+\Delta(r+u)]\Delta\theta(h+\Delta h) \cos \Delta\varphi + 2\sigma_\theta \Delta s \left(h + \frac{1}{2}\Delta h\right) \sin \frac{\Delta\theta}{2} \cos \varphi - p\Delta s(r+u)\Delta\theta \sin \frac{\Delta\varphi}{2} = 0$$

When $\Delta(r+u)$ approaches zero as a limit, the differential equation of equilibrium may be obtained:

$$(r+u) \frac{d(\sigma_r h)}{d(r+u)} = h(\sigma_\theta - \sigma_r) \quad (9)$$

A cap of the membrane bounded by radius $r+u$ and the forces acting on it are shown in figure 2. Summing up the forces in the z -direction yields

$$p\pi(r+u)^2 = \sigma_r \frac{dw}{ds} 2\pi h(r+u)$$

or

$$\left[\frac{dw}{d(r+u)}\right]^2 = \frac{1}{\left[\frac{2h\sigma_r}{p(r+u)}\right]^2 - 1} \quad (10)$$

FIGURE 2.—Cap of membrane with radius $r+u$ in deformed state.

Equations of strains.—Inasmuch as the element at radius r , defined by $\Delta\theta$ and Δr in the undeformed state, is moved by the application of pressure p (fig. 1) to radius $r+u$ and defined by $\Delta\theta$ and Δs , by use of equation (8) the strains are

$$\epsilon_r = \log_e \frac{ds}{dr}$$

$$\epsilon_\theta = \log_e \frac{r+u}{r}$$

$$\epsilon_z = \log_e \frac{h}{h_{init}}$$

Then

$$\epsilon_r = \frac{d(r+u)}{dr} \left\{ 1 + \left[\frac{dw}{d(r+u)} \right]^2 \right\}^{1/2} \quad (11a)$$

$$\epsilon_\theta = \frac{r+u}{r} \quad (11b)$$

$$\epsilon_z = \frac{h}{h_{init}} \quad (11c)$$

ROTATING DISK

Equation of equilibrium.—A disk of radius b and thickness h , rotating about its axis with angular speed ω , and an element

taken at radius $r+u$, defined by $\Delta\theta$ and $\Delta(r+u)$, are shown in figure 3 with all the external forces acting on the element.

FIGURE 3.—Rotating disk and its element.

Summing up all forces acting on the element in the radial direction yields

$$\begin{aligned} &\sigma_r(r+u)h\Delta\theta - (\sigma_r + \Delta\sigma_r)[r+u+\Delta(r+u)]\Delta\theta(h+\Delta h) + \\ &2\sigma_\theta[\Delta(r+u)] \left(h + \frac{1}{2}\Delta h\right) \sin \frac{\Delta\theta}{2} - \\ &\omega^2 \left[r+u + \frac{1}{2}\Delta(r+u)\right] \frac{\rho\pi[(r+\Delta r)^2 - r^2]\Delta\theta}{2\pi} h_{init} = 0 \end{aligned}$$

When $\Delta(r+u)$ approaches zero as a limit, the following equation of equilibrium is obtained:

$$(r+u) \frac{d(\sigma_r h)}{d(r+u)} = (\sigma_\theta - \sigma_r)h - \rho\omega^2 r^2 h_{init} \frac{r+u}{r} \frac{dr}{d(r+u)} \quad (12)$$

Equations of strains.—The strains are

$$\epsilon_r = \frac{d(r+u)}{dr} \quad (13a)$$

$$\epsilon_\theta = \frac{r+u}{r} \quad (13b)$$

$$\epsilon_z = \frac{h}{h_{init}} \quad (13c)$$

INFINITE PLATE WITH CIRCULAR HOLE OR FLAT RING RADIALLY STRESSED

An infinite plate uniformly stressed in its plane in all directions and having a circular hole is shown in figure 4. The whole system is equivalent to a very large circular plate of radius c with a small concentric circular hole radially subjected to the same uniform stress σ on the outer boundary. The solution obtained for such a plate within any radius b can also be considered as a solution of a flat ring with outer radius b and inner radius a , that is, uniformly loaded at the outer boundary with the radial stress σ_b obtained in the plate solution.

The equations for this case can be obtained in a manner similar to the two previous cases, or by simply setting dw/dr and w equal to zero in equations for the membrane, or by setting ω equal to zero in the equation for the rotating disk.

EQUATIONS OF EQUILIBRIUM AND COMPATIBILITY IN TERMS OF PRINCIPAL STRESSES AND STRAINS

CIRCULAR MEMBRANE UNDER PRESSURE

A set of ten independent equations (equations (1a), (3), (5b), (6a), (6b), (9), (10), (11a), (11b), and (11c)) involving the ten unknowns σ_r , σ_θ , ϵ_r , ϵ_θ , ϵ_z , γ , τ , h , u , and w define the problem of the circular membrane under pressure. If equation (11b) is differentiated with respect to r and combined with equation (11a),

$$r \frac{d\epsilon_\theta}{dr} = \frac{e^{(\epsilon_r - \epsilon_\theta)}}{\left\{ 1 + \left[\frac{dw}{d(r+u)} \right]^2 \right\}^{1/2}} - 1 \quad (14)$$

Substituting equation (10) in equation (14) to eliminate w yields the following equation of compatibility:

$$r \frac{d\epsilon_\theta}{dr} = e^{(\epsilon_r - \epsilon_\theta)} \left\{ 1 - \left[\frac{p(r+u)}{2h\sigma_r} \right]^2 \right\}^{1/2} - 1 \quad (15)$$

Equations (9) and (15) can be simplified by using equations (11) to eliminate u and h , which results in

$$r \frac{d\sigma_r}{dr} + \sigma_r r \frac{d\epsilon_z}{dr} = (\sigma_\theta - \sigma_r) e^{(\epsilon_r - \epsilon_\theta)} \left\{ 1 - \left[\frac{rpe^{(\epsilon_\theta - \epsilon_z)}}{2h_{init}\sigma_r} \right]^2 \right\}^{1/2} \quad (16)$$

and

$$r \frac{d\epsilon_\theta}{dr} = e^{(\epsilon_r - \epsilon_\theta)} \left\{ 1 - \left[\frac{rpe^{(\epsilon_\theta - \epsilon_z)}}{2h_{init}\sigma_r} \right]^2 \right\}^{1/2} - 1 \quad (17)$$

The ten equations defining this problem are now reduced to seven independent equations, (1a), (6a), (6b), (5b), (3), (16), and (17), with the seven unknowns σ_r , σ_θ , ϵ_r , ϵ_θ , ϵ_z , τ , and γ .

The solution of the problem is simplified by introducing an arbitrary constant k into equations (16) and (17):

$$\left. \begin{aligned} r \frac{d\sigma_r}{d\left(\frac{r}{k}\right)} + \sigma_r r \frac{d\epsilon_z}{d\left(\frac{r}{k}\right)} &= (\sigma_\theta - \sigma_r) e^{(\epsilon_r - \epsilon_\theta)} \left\{ 1 - \left[\frac{pk}{h_{init}k} \frac{r}{2\sigma_r} e^{(\epsilon_\theta - \epsilon_z)} \right]^2 \right\}^{1/2} \\ r \frac{d\epsilon_\theta}{d\left(\frac{r}{k}\right)} &= e^{(\epsilon_r - \epsilon_\theta)} \left\{ 1 - \left[\frac{pk}{h_{init}k} \frac{r}{2\sigma_r} e^{(\epsilon_\theta - \epsilon_z)} \right]^2 \right\}^{1/2} - 1 \end{aligned} \right\} \quad (18)$$

where k is any arbitrary unknown constant with the dimension of length. By use of the two parameters r/k and pk/h_{init} , it is possible to solve the problem in a simple, direct way without the use of the iteration. This will be further discussed in the section "Methods of Numerical Integration."

ROTATING DISK

For the rotating disk there are nine independent relations (equations (1a), (3), (5b), (6a), (6b), (12), (13a), (13b), and (13c)) with the nine unknowns σ_r , σ_θ , ϵ_r , ϵ_θ , ϵ_z , γ , τ , h , and u . If equation (13b) is differentiated with respect to r and combined with equation (13a), the following compatibility equation is obtained:

$$r \frac{d\epsilon_\theta}{dr} = e^{(\epsilon_r - \epsilon_\theta)} - 1 \quad (19)$$

(a) Infinite plate with circular hole uniformly stressed in its plane in all directions.
(b) Flat ring radially stressed.
(c) Element.

FIGURE 4.—Infinite plate with circular hole, flat ring radially stressed, and its element in deformed state.

As in the case of the membrane, u and h can be eliminated from the equilibrium equation (12) by using equations (13), which yields

$$r \frac{d\sigma_r}{dr} + \sigma_r r \frac{d\epsilon_z}{dr} = (\sigma_\theta - \sigma_r) e^{(\epsilon_r - \epsilon_\theta)} - \rho \omega^2 r^2 e^{(-\epsilon_z)} \quad (20)$$

The nine equations defining this problem are now reduced to seven independent equations, (1a), (6a), (6b), (5b), (3), (19), and (20), with the seven unknowns σ_r , σ_θ , ϵ_r , ϵ_θ , ϵ_z , τ , and γ .

The solution of the problem is made simpler by introducing an arbitrary constant k into equations (19) and (20):

$$\left. \begin{aligned} r \frac{d\sigma_r}{d\left(\frac{r}{k}\right)} + \sigma_r r \frac{d\epsilon_z}{d\left(\frac{r}{k}\right)} &= (\sigma_\theta - \sigma_r) e^{(\epsilon_r - \epsilon_\theta)} - \rho (\omega k)^2 \left(\frac{r}{k}\right)^2 e^{(-\epsilon_z)} \\ r \frac{d\epsilon_\theta}{d\left(\frac{r}{k}\right)} &= e^{(\epsilon_r - \epsilon_\theta)} - 1 \end{aligned} \right\} \quad (21)$$

By use of the parameters r/k and ωk instead of r and ω , a simple direct solution is possible for any arbitrary value of ωk with k to be determined by the boundary condition.

INFINITE PLATE WITH CIRCULAR HOLE OR
FLAT RING RADIALLY STRESSED

The equations of equilibrium and compatibility for the infinite plate with a circular hole or the flat ring radially stressed are:

$$\left. \begin{aligned} \frac{r}{a} \frac{d\sigma_r}{d\left(\frac{r}{a}\right)} + \sigma_r \frac{r}{a} \frac{d\epsilon_z}{d\left(\frac{r}{a}\right)} &= (\sigma_\theta - \sigma_r) e^{(\epsilon_r - \epsilon_\theta)} \\ \frac{r}{a} \frac{d\epsilon_\theta}{d\left(\frac{r}{a}\right)} &= e^{(\epsilon_r - \epsilon_\theta)} - 1 \end{aligned} \right\} \quad (22)$$

The problem is defined by equations (22) together with equations (1a), (6a), (6b), (5b), and (3) (seven equations with seven unknowns).

EQUATIONS OF EQUILIBRIUM AND COMPATIBILITY IN
TERMS OF OCTAHEDRAL SHEAR STRAIN AND PARAM-
ETER INDICATING RATIO OF PRINCIPAL STRESSES

In the preceding section, displacements are eliminated from the equations, which result in seven equations involving the seven unknown quantities σ_r , σ_θ , ϵ_r , ϵ_θ , ϵ_z , τ , and γ . The quantity ϵ_z can be expressed in terms of ϵ_r and ϵ_θ (from equation (1a)). Two of the four unknowns σ_r , σ_θ , ϵ_r , and ϵ_θ can be eliminated by using equations (6a) and (6b) or (7). The quantity τ is a known function of γ that is experimentally determined. The problem is then reduced to one involving three unknowns. Obtaining the solution of the resulting equations is not, however, a simple matter; the iterative process is usually needed.

It is proposed that this can be avoided by using the following transformation:

$$\sigma_\theta + \sigma_r = 3\sqrt{2}\tau \sin \alpha$$

$$\sigma_\theta + \sigma_r = \sqrt{6}\tau \cos \alpha$$

or

$$\left. \begin{aligned} \sigma_r &= \sqrt{\frac{3}{2}}\tau(\sqrt{3}\sin \alpha - \cos \alpha) \\ \sigma_\theta &= \sqrt{\frac{3}{2}}\tau(\sqrt{3}\sin \alpha + \cos \alpha) \end{aligned} \right\} \quad (23)$$

Then σ_r and σ_θ satisfy equation (5a), because the yielding surfaces are ellipses according to the deformation theory. The octahedral shear stress τ , a function of γ , in the preceding equations varies with r/k and also with loading. Such a transformation has been used for ideally plastic material ($\tau = \text{constant}$) by Nadai in the section "Yielding in Thin Plate With Circular Hole or Flat Rings Radially Stressed"

(reference 1, p. 189) and for a rotating disk (reference 2). From equations (6a), (6b), and (23), the principal strains also can be expressed in terms of γ and α :

$$\left. \begin{aligned} \epsilon_r &= \frac{\gamma}{2\sqrt{2}}(\sin \alpha - \sqrt{3}\cos \alpha) \\ \epsilon_\theta &= \frac{\gamma}{2\sqrt{2}}(\sin \alpha + \sqrt{3}\cos \alpha) \end{aligned} \right\} \quad (24)$$

The equations of equilibrium and compatibility for the three problems considered herein are then obtained in terms of γ and α in the following form:

$$\left. \begin{aligned} A \frac{r}{k} \frac{d\alpha}{d\left(\frac{r}{k}\right)} + B \frac{r}{k} \frac{d\gamma}{d\left(\frac{r}{k}\right)} &= C \\ D \frac{r}{k} \frac{d\alpha}{d\left(\frac{r}{k}\right)} + E \frac{r}{k} \frac{d\gamma}{d\left(\frac{r}{k}\right)} &= F \end{aligned} \right\} \quad (25)$$

where the coefficients A , B , C , D , E , and F are functions of α , γ , and r/k . For the circular membrane under pressure, from equation (18),

$$\left. \begin{aligned} A &= (\sqrt{3}\cos \alpha + \sin \alpha) - (\sqrt{3}\sin \alpha - \cos \alpha) \frac{\gamma \cos \alpha}{\sqrt{2}} \\ B &= (\sqrt{3}\sin \alpha - \cos \alpha) \left(\frac{\gamma}{\tau} \frac{d\tau}{d\gamma} - \frac{\gamma \sin \alpha}{\sqrt{2}} \right) \frac{1}{\gamma} \\ C &= 2(\cos \alpha) e^{(-\sqrt{\frac{3}{2}}\gamma \cos \alpha)} \\ D &= (\sqrt{3}\sin \alpha - \cos \alpha) \gamma \\ E &= -(\sqrt{3}\cos \alpha + \sin \alpha) \\ F &= 2\sqrt{2} \\ &\left\{ 1 - e^{(-\sqrt{\frac{3}{2}}\gamma \cos \alpha)} \left[1 - \frac{e^{\sqrt{\frac{3}{2}}(\sqrt{3}\sin \alpha + \cos \alpha)\gamma}}{6\tau^2(\sqrt{3}\sin \alpha - \cos \alpha)^2} \left(\frac{r}{k}\right)^2 \left(\frac{pk}{h_{init}}\right)^2 \right]^{1/2} \right\} \end{aligned} \right\} \quad (26)$$

For the rotating disk, from equation (21),

$$\left. \begin{aligned} A &= (\sqrt{3}\cos \alpha + \sin \alpha) - (\sqrt{3}\sin \alpha - \cos \alpha) \frac{\gamma \cos \alpha}{\sqrt{2}} \\ B &= (\sqrt{3}\sin \alpha - \cos \alpha) \left(\frac{\gamma}{\tau} \frac{d\tau}{d\gamma} - \frac{\gamma \sin \alpha}{\sqrt{2}} \right) \frac{1}{\gamma} \\ C &= 2(\cos \alpha) e^{(-\sqrt{\frac{3}{2}}\gamma \cos \alpha)} - \sqrt{\frac{2}{3}} \rho(\omega k)^2 \frac{1}{\tau} \left(\frac{r}{k}\right)^2 e^{\frac{\gamma}{\sqrt{2}}\sin \alpha} \\ D &= (\sqrt{3}\sin \alpha - \cos \alpha) \gamma \\ E &= -(\sqrt{3}\cos \alpha + \sin \alpha) \\ F &= 2\sqrt{2} \left[1 - e^{(-\sqrt{\frac{3}{2}}\gamma \cos \alpha)} \right] \end{aligned} \right\} \quad (27)$$

For the infinite plate with a circular hole, from equation (22),

$$\left. \begin{aligned} A &= (\sqrt{3} \cos \alpha + \sin \alpha) - (\sqrt{3} \sin \alpha - \cos \alpha) \frac{\gamma \cos \alpha}{\sqrt{2}} \\ B &= (\sqrt{3} \sin \alpha - \cos \alpha) \left(\frac{\gamma}{\tau} \frac{d\tau}{d\gamma} - \frac{\gamma \sin \alpha}{\sqrt{2}} \right) \frac{1}{\gamma} \\ C &= 2 (\cos \alpha) e^{(-\sqrt{\frac{3}{2}} \gamma \cos \alpha)} \\ D &= (\sqrt{3} \sin \alpha - \cos \alpha) \gamma \\ E &= -(\sqrt{3} \cos \alpha + \sin \alpha) \\ F &= 2\sqrt{2} \left[1 - e^{(-\sqrt{\frac{3}{2}} \gamma \cos \alpha)} \right] \end{aligned} \right\} \quad (28)$$

With these transformations, the solution of the problems is reduced to simply a numerical integration of the two simultaneous differential equations (equations (25)) involving the two unknowns γ and α . Furthermore, the parameter γ , being the octahedral shear strain, directly indicates the stage of plastic deformation at any point under any load. (In plastic problems, according to the deformation theory, the individual stress and strain distributions cannot give as clear a picture of the stage of plastic deformation as can the octahedral shear strain.) Also, the parameter α indicates the ratio of the principal stresses or strains. At any point, if α remains constant during loading, the ratio of principal stresses at that point remains fixed. The value of α obtained at each point in the calculation during loading directly indicates whether or not the deformation theory is applicable to the problem.

The value of α is known at the boundaries or the center. This value can be determined from equations (23) and (24). For the circular membrane under pressure, when $r/b=0$,

$$\sigma_r = \sigma_\theta$$

$$\alpha = \frac{\pi}{2} = 1.5708$$

when $r/b=1$,

$$\epsilon_\theta = 0$$

$$\alpha = \frac{2}{3} \pi = 2.0944$$

For the rotating disk without a hole, when $r/b=0$,

$$\sigma_r = \sigma_\theta$$

$$\alpha = \frac{\pi}{2} = 1.5708$$

when $r/b=1$,

$$\sigma_r = 0$$

$$\alpha = \frac{\pi}{6} = 0.5236$$

For the rotating disk with a hole, when $r/a=1$ and $r/b=1$,

$$\sigma_r = 0$$

$$\alpha = \frac{\pi}{6} = 0.5236$$

For the infinite plate with a circular hole, when $r/a=1$,

$$\sigma_r = 0$$

$$\alpha = \frac{\pi}{6} = 0.5236$$

when r/a approaches c/a or a value that is large compared with 1,

$$\sigma_r = \sigma_\theta$$

$$\alpha = \frac{\pi}{2} = 1.5708$$

METHODS OF NUMERICAL INTEGRATION

Two methods are developed to solve the differential equations (25). In the first method, the differential equations are numerically integrated along r/k , which is considered the independent variable. (In the second method, α is considered the independent variable.) Because many terms in the equations are trigonometric functions of α , the use of α as the independent variable considerably reduces the work of computation.

Numerical integration with r/k as independent variable.—Equation (25) can be written in the following forms:

$$\left. \begin{aligned} \frac{r}{k} \frac{d\alpha}{d\left(\frac{r}{k}\right)} &= \frac{CE - FB}{AE - DB} \\ \frac{r}{k} \frac{d\gamma}{d\left(\frac{r}{k}\right)} &= \frac{FA - CD}{EA - BD} \end{aligned} \right\} \quad (29)$$

At any point, if α and γ are known, $\frac{d\alpha}{d(r/k)}$ and $\frac{d\gamma}{d(r/k)}$ can be

calculated by equations (29). At the boundaries or the center, α is known, but γ is determined by the load. Only one value (unknown) of γ corresponding to a particular load exists on each boundary; therefore it is difficult to start the numerical integrations on the boundary with the correct value of γ corresponding to a given load. Also, in plastic problems covering the strain-hardening range, the method of superposition is invalid. Usually, a method of iteration is used to solve the problem (for example, references 3 and 4). In the method presented herein, an arbitrary but unknown constant k has been introduced in equations (18), (21), and (22). For the cases considered, the terms in the equations that involve load are always multiplied by r , so that $\left(\frac{pr}{h_{init}}\right)^2$ can be written as $\left(\frac{pk}{h_{init}}\right)^2 \left(\frac{r}{k}\right)^2$ in equations (18) and (26) and $(\omega r)^2$ as $(\omega k)^2 \left(\frac{r}{k}\right)^2$ in equations (21) and (27).

The numerical integration then can be started at the inner boundary (or at the center if there is no circular hole at the center) by using the known values of α_o , a desired value of γ_o , and an arbitrary value of $\left(\frac{pk}{h_{init}}\right)^2$ for the membrane or of $(\omega k)^2$ for the rotating disk. The numerical integrations can then be carried out, obtaining values of α and γ at different values of r/k , until α progressively reaches the value that satisfies the outer boundary condition. Because the value of r is known at the boundaries, the value of k can be determined for the selected value of γ_o . The number of points and the formulas used in the calculation depend on the accuracy required (references 19 and 20). If the formula for evaluating definite integrals is applied after using the forward integration formula (references 19 and 20), great accuracy can easily be obtained.

The procedure used herein to obtain solutions is the same for each problem. Calculations are started from the inner boundary (or from the center if there is no circular hole at the center) with the known value of α_o , the desired value of γ_o , and the arbitrary loading term. The parameter α_o is equal to $\pi/2$ at $r/b=0$ for the membrane and for the solid rotating disk and is equal to $\pi/6$ at $r/a=1$ for the infinite plate with a circular hole and for the rotating disk with a hole. The arbitrary loading terms are $\left(\frac{pk}{h_{init}}\right)^2$ and $(\omega k)^2$ for the membrane and the rotating disk, respectively. Then $\left[\frac{d\alpha}{d(r/k)}\right]_o$ and $\left[\frac{d\gamma}{d(r/k)}\right]_o$, corresponding to α_o and γ_o at the inner boundary or the center, are obtained from equations (29). The following formulas for forward integration are used to determine the first approximate values of α and γ at the next point (α_1^* and γ_1^*):

$$\begin{aligned}\alpha_1^* &= \alpha_o + \left[\left(\frac{r}{k} \right)_1 - \left(\frac{r}{k} \right)_o \right] \left[\frac{d\alpha}{d\left(\frac{r}{k} \right)} \right]_o \\ \gamma_1^* &= \gamma_o + \left[\left(\frac{r}{k} \right)_1 - \left(\frac{r}{k} \right)_o \right] \left[\frac{d\gamma}{d\left(\frac{r}{k} \right)} \right]_o\end{aligned}\quad (30a)$$

By substitution of α_1^* and γ_1^* into equation (29), approximate values of $\left[\frac{d\alpha}{d\left(\frac{r}{k}\right)}\right]_1$ and $\left[\frac{d\gamma}{d\left(\frac{r}{k}\right)}\right]_1$ are obtained and

the second approximate values of α_1 and γ_1 (α_1^{**} and γ_1^{**}) can be computed from the following formulas:

$$\begin{aligned}\alpha_1^{**} &= \alpha_o + \frac{1}{2} \left[\left(\frac{r}{k} \right)_1 - \left(\frac{r}{k} \right)_o \right] \left\{ \left[\frac{d\alpha}{d\left(\frac{r}{k} \right)} \right]_o + \left[\frac{d\alpha}{d\left(\frac{r}{k} \right)} \right]_1^* \right\} \\ \gamma_1^{**} &= \gamma_o + \frac{1}{2} \left[\left(\frac{r}{k} \right)_1 - \left(\frac{r}{k} \right)_o \right] \left\{ \left[\frac{d\gamma}{d\left(\frac{r}{k} \right)} \right]_o + \left[\frac{d\gamma}{d\left(\frac{r}{k} \right)} \right]_1^* \right\}\end{aligned}\quad (30b)$$

The values of α_1^{**} and γ_1^{**} are substituted into equation (29)

again in order to calculate the values of $\left[\frac{d\alpha}{d\left(\frac{r}{k}\right)}\right]_1$ and $\left[\frac{d\gamma}{d\left(\frac{r}{k}\right)}\right]_1$. By use of the following formulas for evaluating

definite integrals, the volumes of α_1 and γ_1 are calculated:

$$\begin{aligned}\alpha_1 &= \alpha_o + \frac{1}{2} \left[\left(\frac{r}{k} \right)_1 - \left(\frac{r}{k} \right)_o \right] \left\{ \left[\frac{d\alpha}{d\left(\frac{r}{k} \right)} \right]_o + \left[\frac{d\alpha}{d\left(\frac{r}{k} \right)} \right]_1 \right\} \\ \gamma_1 &= \gamma_o + \frac{1}{2} \left[\left(\frac{r}{k} \right)_1 - \left(\frac{r}{k} \right)_o \right] \left\{ \left[\frac{d\gamma}{d\left(\frac{r}{k} \right)} \right]_o + \left[\frac{d\gamma}{d\left(\frac{r}{k} \right)} \right]_1 \right\}\end{aligned}\quad (30c)$$

This procedure is applied to the next point, and so forth, until the value of α reaches the required value of α_b at the outside boundary ($\alpha_b = 2/3 \pi$ at $r/b=1$ for the membrane, $\alpha_b = \pi/6$ at $r/b=1$ for the rotating disk, and $\alpha_b = \pi/2$ at $r/a=c/a$ for the thin plate with a circular hole). Inasmuch as

$$\left(\frac{r}{k} \right)_{a-\alpha_b} = \frac{b}{k}$$

the loading terms are determined as follows:

For the membrane,

$$\left(\frac{pb}{h_{init}} \right)^2 = \left(\frac{pk}{h_{init}} \right)^2 \left(\frac{b}{k} \right)^2 \quad (31a)$$

For the rotating disk,

$$(\omega b)^2 = (\omega k)^2 \left(\frac{b}{k} \right)^2 \quad (31b)$$

For the infinite plate with a circular hole,

$$t_c = \sigma h_c \left(\frac{r+u}{r} \right)_c = \sigma h_{init} e^{-\epsilon_r} = \sigma h_{init} e^{-\frac{\gamma_c}{2\sqrt{2}}} \quad (31c)$$

or for the flat ring radially stressed at the outside diameter b ,

$$t_b = (\sigma_r)_b h_b \left(\frac{r+u}{r} \right)_b = (\sigma_r)_b h_{init} e^{-\frac{\gamma_b}{2\sqrt{2}} (\sin \alpha_b - \sqrt{3} \cos \alpha_b)} \quad (31d)$$

where t_c and t_b are the tensions per unit original circumferential length at $r=c$ and $r=b$, respectively.

Numerical integration with α as independent variable.—Equations (29) can be written in the following forms:

$$\begin{aligned}\frac{d\gamma}{d\alpha} &= \frac{FA - CD}{CE - FB} \\ \frac{d\left(\frac{r}{k} \right)}{d\alpha} &= \frac{AE - DB}{CE - BF} \frac{r}{k}\end{aligned}\quad (32)$$

By use of equations (26) to (28) and expansion of $e^{f(\alpha, \gamma)}$ into a series, the following equations are obtained:

For the circular membrane, from equations (26),

$$\left. \begin{aligned} CE-BF &= 2GJ - \left[2\sqrt{3}HJg\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right)f_1(\alpha, \gamma) + 2\sqrt{3} \right] j\left(\alpha, \gamma, \frac{r}{k}, \frac{pk}{h_{init}}\right) \\ AF-CD &= 2\sqrt{2}L - 2HJ\gamma - 2\sqrt{2}Lf_2(\alpha, \gamma)j\left(\alpha, \gamma, \frac{r}{k}, \frac{pk}{h_{init}}\right) \\ AE-BD &= -L^2 - J^2g\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right) \end{aligned} \right\} \quad (33)$$

For the rotating disk, from equations (27),

$$\left. \begin{aligned} CE-BF &= -2HL - 2\sqrt{3}HJg\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right)f_1(\alpha, \gamma) + L\frac{K_2}{\tau}\left(\frac{r}{k}\right)^2f_3(\alpha, \gamma) \\ AF-CD &= \left\{ 8H^2 - 2\sqrt{3}HL[1-f_1(\alpha, \gamma)] + J\frac{K_2}{\tau}\left(\frac{r}{k}\right)^2f_3(\alpha, \gamma) \right\} \gamma \\ AE-BD &= -L^2 - J^2g\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right) \end{aligned} \right\} \quad (34)$$

For the infinite plate with a circular hole, from equations (28),

$$\left. \begin{aligned} CE-BF &= -2HL - 2\sqrt{3}HJg\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right)f_1(\alpha, \gamma) \\ AF-CD &= \{ 8H^2 - 2\sqrt{3}HL[1-f_1(\alpha, \gamma)] \} \gamma \\ AE-BD &= -L^2 - J^2g\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right) \end{aligned} \right\} \quad (35)$$

where

$$G = \sin \alpha$$

$$H = \cos \alpha$$

$$J = \sqrt{3} \sin \alpha - \cos \alpha$$

$$L = \sqrt{3} \cos \alpha + \sin \alpha$$

$$K_1 = \left(\frac{pk}{h_{init}}\right)^2$$

$$K_2 = \sqrt{\frac{2}{3}} \rho(\omega k)^2$$

and

$$f_1(\alpha, \gamma) = \frac{1}{\sqrt{\frac{3}{2}}(\cos \alpha)\gamma} \left[1 - e^{-\sqrt{\frac{3}{2}}(\cos \alpha)\gamma} \right]$$

$$= 1 - \frac{1}{2} \sqrt{\frac{3}{2}}(\cos \alpha)\gamma + \frac{1}{4}(\cos^2 \alpha)\gamma^2 - \dots$$

$$f_2(\alpha, \gamma) = e^{-\sqrt{\frac{3}{2}}(\cos \alpha)\gamma}$$

$$= 1 - \sqrt{\frac{3}{2}}(\cos \alpha)\gamma + \frac{1}{2} \times \frac{3}{2}(\cos^2 \alpha)\gamma^2 -$$

$$\frac{1}{4} \sqrt{\frac{3}{2}}(\cos^3 \alpha)\gamma^3 + \dots$$

$$= 1 - \sqrt{\frac{3}{2}}(\cos \alpha)\gamma f_1(\alpha, \gamma)$$

$$f_3(\alpha, \gamma) = e^{\frac{\gamma}{\sqrt{2}} \sin \alpha}$$

$$= 1 + \left(\frac{1}{\sqrt{2}} \sin \alpha\right)\gamma + \frac{1}{2} \left(\frac{1}{\sqrt{2}} \sin \alpha\right)^2 \gamma^2 +$$

$$\frac{1}{6} \left(\frac{1}{\sqrt{2}} \sin \alpha\right)^3 \gamma^3 + \dots$$

$$g\left(\alpha, \gamma, \frac{\gamma}{\tau} \frac{d\tau}{d\gamma}\right) = \frac{\gamma}{\tau} \frac{d\tau}{d\gamma} - \sqrt{\frac{3}{2}} \frac{\gamma}{\sqrt{3} \sin \alpha - \cos \alpha} = \frac{\gamma}{\tau} \frac{d\tau}{d\gamma} - \sqrt{\frac{3}{2}} \frac{\gamma}{J}$$

$$j\left(\alpha, \gamma, \frac{r}{k}, \frac{pk}{h_{init}}\right) = \left[1 - \frac{e^{\sqrt{\frac{3}{2}}\gamma(\sqrt{3} \sin \alpha + \cos \alpha)}}{6\tau^2(\sqrt{3} \sin \alpha - \cos \alpha)^2} \left(\frac{r}{k}\right)^2 \left(\frac{pk}{h_{init}}\right)^2 \right]^{1/2}$$

$$= \left[1 - \frac{K_1}{6J^2} \left(\frac{1}{\tau} \frac{r}{k}\right)^2 \frac{f_3(\alpha, \gamma)}{f_2(\alpha, \gamma)} \right]^{1/2}$$

The symbols G , H , J , and L are trigonometric functions of α only; K_1 and K_2 are arbitrary loading constants. The symbols f_1 , f_2 , f_3 , and g are functions of α and γ ; j is a function of α , γ , and r/k .

For the solution of an infinite plate with a circular hole α is the independent variable. The procedure of numerical integration is similar to that used in the method in which r/k is the independent variable. The first four terms of the series of $e^{f(\alpha, \gamma)}$ are used; the accuracy of the result is the same as that of the previous method, but computation is reduced by one half.

Both methods presented herein are used to obtain the solutions for the given values of γ_o . The purpose of the present paper is to obtain solutions for the entire strain-hardening range and the methods developed are very convenient for this purpose. If, however, a solution for only a particular value of loading is required, it can be obtained by interpolating between values obtained from two or three solutions corresponding to loading near the specified value.

NUMERICAL EXAMPLES

Membrane.—In order to compare the results for the circular membrane obtained by the method developed herein with those obtained by Gleyzal (reference 3), one numerical solution for infinitesimal strain is calculated by using the $\tau(\gamma)$ curve of the tensile test in figure 1 of reference 3. Inasmuch as reference 3 states that: "For simplicity, strain will be taken to mean conventional strain $(ds - ds_o)/ds_o$ where ds and ds_o are final and initial arc length, respectively.", equations (25a) and (36) given in appendix A for infinitesimal strain are used. The calculation is started at $r/k=0.005$. Values of $\alpha_o=1.5708$, $\gamma_o=0.0299$, and $pk/h_{int}=55,920$ are used.

Rotating disk.—Numerical solutions for the rotating disk

FIGURE 5.—Octahedral shear stress-strain curves.

for finite strain (equations (25) and (27)) are calculated. The $\tau(\gamma)$ curves of two materials, Inconel X and 16-25-6, are plotted in figure 5 (a). These data were supplied by W. F. Brown, Jr., H. Schwartzbart, and M. H. Jones. The same $\tau(\gamma)$ curves are plotted on logarithmic coordinates in figure 5 (b). These materials, Inconel X and 16-25-6, for which τ is not a power function of γ , were chosen so that more general information can be obtained. The given octahedral shear stress-strain curves (fig. 5) of these two materials have not been corrected for the triaxiality and nonuniform stress distribution introduced by necking and consequently do not represent the exact stress-strain relation after necking of these two materials. The solutions obtained from the $\tau(\gamma)$ curves of the tensile test after necking can, however, represent the solutions corresponding to materials having the exact $\tau(\gamma)$ curves shown in figure 5 and for simplicity such materials are herein referred to as "Inconel X" and "16-25-6".

The calculation for the solid rotating disk is started at $r/k=0.005$, as in the case of the membrane.

Three solutions are also obtained for the rotating disk with a central hole, using Inconel X. Calculations are started at $r/a=1$.

All numerical examples for the rotating disk are given in the following table:

Solid rotating disk		
Material	γ_o	$K_2 = \sqrt{\frac{2}{3}} \rho (\omega k)^2$
Inconel X	0.04	1×10^3
	.1152	1×10^3
	.30	1×10^3
16-25-6	0.04	1×10^3
	.1152	1×10^3
	.30	2.5×10^3

Rotating disk with central hole		
Material	γ_o	$\sqrt{\frac{2}{3}} \rho (\omega a)^2$
Inconel X	0.30	1×10^4
	.30	2×10^3
	.30	4×10^2

Infinite plate with circular hole.—The calculations for the infinite plate with a circular hole are carried out for the case in which $\sigma_r=0$ at $r/a=1$. The value of α_o at $r/a=1$ is then equal to 0.5236. (When σ_r is different from 0 at $r/a=1$, the corresponding value of α_o should be used.) The same materials as in the previous problem are considered. The numerical examples are:

Material	γ_o
Inconel X	0.04
	.1152
	.1871
	.30
16-25-6	0.04
	.1871
	.30

RESULTS AND DISCUSSIONS

The radial and circumferential stresses σ_r and σ_θ , respectively, obtained for the circular membrane are plotted against r/b in figure 6. Two curves, taken from reference 3, corresponding to calculations for about the same pressure used in the present calculation, are included in the figure for comparison. In the present calculation, the $\tau(\gamma)$ curve given in figure 1 of reference 3 and the same infinitesimal-strain definition based on the original dimension are used. The initial thickness h_{init} is also used for consistency in the calculation rather than the instantaneous thickness h , which is used in reference 3.

The variations of α with the radius for the rotating disk and with the radius for the infinite plate with a circular hole are plotted in figures 7 (a) and 7 (b), respectively, for different loads and materials. The variations of α with γ_o (or loading) at various radii for the rotating disk and the infinite plate with a circular hole are plotted in figures 8 (a) and 8 (b), respectively. Similar curves for the ratio of the principal stresses σ_r/σ_θ are shown in figures 9 (a), 9 (b), and 10. Comparison of figure 7 and figures 9 (a) and 9 (b) shows that the variations of α with radius are very similar to the variations of σ_r/σ_θ with radius, although the relation between α and σ_r/σ_θ is not linear.

Numerical examples for a membrane with a large strain are not calculated herein, because the result of reference 3 is sufficient to give an approximate variation of the ratios of principal stresses along the radius during loading, although the infinitesimal-strain concept is used. The variations of the ratio of principal stresses with radius for different loads, based on the values of σ_r and σ_θ given in figures 8 and 9 of reference 3, are calculated and plotted on figure 9 (c).

FIGURE 7.—Variations of parameter α with proportionate radius distance for Inconel X and 16-25-6.

The values of σ_r are plotted against σ_θ at various radii under different loads for the rotating disk and the infinite plate with a circular hole in figures 11 (a) and 11 (b). The heavy solid and dashed curves represent the values of σ_r and σ_θ at different radii for any given load and are called loading curves. The loading curve moves away from the

FIGURE 8.—Variation of parameter α with maximum octahedral shear strain at different radii.

origin with increasing load. The light solid and dotted lines connecting the different loading curves at a given radius and extending to the origin represent the values of σ_r and σ_θ at different loads for any given radius and are called loading paths. Also shown in the figures are the yielding surfaces, which are ellipses under the deformation theory.

A clear picture of the variation of the ratios of principal stresses in this group of problems with different loads for Inconel X, 16-25-6, and the material used in reference 3 is given in figures 7 to 11. It is evident that the ratios of principal stresses remain essentially constant during loading.

FIGURE 9.—Variations of ratio of principal stresses with proportionate radial distance.

The deformation theory is therefore applicable to this group of problems, at least for the materials considered.

The variations of γ and γ/γ_o with radius are plotted in figures 12 and 13, respectively, for the rotating disk and the infinite plate with a circular hole. It is interesting to note that the curves in figure 13 for different loads for the same material are quite close together. For different materials, the curves of figures 7 and 9 are also close, but the curves of figure 13 are not as close together.

(a) Rotating disk.

(b) Infinite plate with circular hole.

FIGURE 11.—Loading curves, loading paths, and yielding surfaces.

The distributions of principal stresses and principal strains along the radius for the rotating disk and for the infinite plate with a circular hole are plotted in figures 14 and 15, respectively. For comparison, the variations of $\sigma_\theta/(\sigma_\theta)_b$, $\epsilon_\theta/(\epsilon_\theta)_b$, and γ/γ_b with radius for both the elastic and the plastic range are plotted in figures 16 and 17. (The equations for the elastic case are given in appendix B.) If only the stress distributions for the elastic and plastic cases are compared (figs. 16 (a) and 17 (a)), it is seen that the stresses are more uniform in the plastic state; but if the distributions of the principal strains and the octahedral shear strain for the elastic and the plastic cases are compared (figs. 16 (b), 16 (c), 17 (b), and 17 (c)), it is evident that a less-uniform strain distribution is obtained in the plastic state. It is of special interest in the case of the finite plate with a hole to note that with plastic deformation the stress-(tangential stress) concentration factor around the hole is reduced; instead there is a high concentration in principal strain and in octahedral shear

FIGURE 12.—Variation of octahedral shear strain with proportionate radial distance.

(a) Rotating disk.

(b) Infinite plate with hole.

FIGURE 14.—Variation of principal stresses with proportionate radial distance.

strain. A similar conclusion regarding the concentration factor around a circular hole in a tension panel is given in references 21 and 22.

The quantities $\sigma_\theta/(\sigma_\theta)_0$, $\sigma_r/(\sigma_r)_0$, $\epsilon_r/(\epsilon_r)_0$, and $\epsilon_\theta/(\epsilon_\theta)_0$ along the radius for the rotating disk and $\sigma_\theta/(\sigma_\theta)_0$ and $\epsilon_\theta/(\epsilon_\theta)_0$ for the infinite plate with a circular hole are plotted in figures 18 and 19, respectively. The curves representing $\sigma_r/(\sigma_r)_0$, $\epsilon_r/(\epsilon_r)_0$, and $\epsilon_\theta/(\epsilon_\theta)_0$ for Inconel X and 16-25-6 and different values of γ_0 are close together; but the curves of $\sigma_\theta/(\sigma_\theta)_0$ are quite far apart for the two materials, as well as for different values of γ_0 .

The relation between the rotating-speed function $\rho(\omega b)^2$

and γ_0 for the rotating disk and the relation between the tension per unit original circumferential length t_b/h_{init} and γ_0 for the infinite plate with a hole are plotted in figures 20 (a) and 20 (b), respectively. It is shown in these figures that $\rho(\omega b)^2$ and t_b/h_{init} increase considerably for Inconel X and increase only slightly for 16-25-6 as the value of γ_0 increases from 0.04 to 0.30.

Figures 7, 13, and 16 to 19 show that for the plate with a hole, the variations of α , γ/γ_0 , $\epsilon_r/(\epsilon_r)_0$, and $\epsilon_\theta/(\epsilon_\theta)_0$ with radius are essentially independent of the value of γ_0 for the plate and the $\tau(\gamma)$ curve of the material, at least for the materials considered. These results show that the deformation that

can be accepted by the plate before failure depends mainly on the maximum octahedral shear strain (or ductility) of the material, which would not be true if the strain distributions were a function of the $\tau(\gamma)$ curve. For the rotating disk,

(a) Solid rotating disk.
(b) Flat ring radially stressed.

FIGURE 20.—Relation between rotating-speed function and maximum octahedral shear strain for disk and relation between tension per unit original circumferential length for plate.

however, a slight effect of γ_0 and the $\tau(\gamma)$ curve is apparent on the strains; this effect seems to be caused by the body-force term of the disk.

The stress distribution that will determine the load which a member can sustain is now considered. Figures 16 to 19 show that the variation of $\sigma_\theta/(\sigma_\theta)_0$ with radius depends on the $\tau(\gamma)$ curve of the material and on the value of γ_0 for the member. Figure 20 indicates that the load also depends on the $\tau(\gamma)$ curve. It therefore follows that the added load that the member can sustain between the onset of yielding and failure depends on the $\tau(\gamma)$ curve of the material. The octahedral shear (or effective) stress and strain curve of the material should be used as a criterion in selecting a material

 (a) Variation of parameter α with proportionate radial distance.

(b) Variation of octahedral shear strain with proportionate radial distance.

(c) Variation of principal stresses with proportionate radial distance.

 FIGURE 21.—Rotating disk with hole. Inconel X; γ_0 , 0.3000.

FIGURE 21.—Continued. Rotating disk with hole. Inconel X; γ_0 , 0.3000.

for a particular member under a particular loading condition, because consideration of the maximum octahedral shear strain only (or ductility only) of the material is insufficient.

The variations of α , γ , σ_r , σ_θ , ϵ_r , ϵ_θ , and γ/γ_b with radius for three rotating disks with a hole are shown in figure 21. The values of the ratios of outer to inner radius b/a of these three disks equal 5.32, 12.45, and 28.12. These disks were made of Inconel X and had a maximum octahedral shear strain γ_0 of 0.3 at the inner radius of the disk. The tangential stress σ_θ , the tangential strain ϵ_θ , and the octahedral shear strain γ are much less uniform for the disk with a hole than for a solid rotating disk. The ratio of maximum to minimum octahedral shear strain γ_0/γ_b is equal to 7.41 for a disk with $b/a=5.32$, 11.75 for a disk with $b/a=12.45$, and 14.1 for a disk with $b/a=28.12$; for a solid disk of the same material, the ratio γ_0/γ_b is about 5.3.

The load, rotating-speed function $\rho(\omega b)^2$, for disks of Inconel X reaching a maximum octahedral shear strain γ_0 of 0.3 at the inner radius of the disk and having different ratios of inner to outer radius a/b is represented by the solid curve

(e) Variation of ratio of octahedral shear strain to minimum octahedral shear strain at outer radius with proportionate radial distance.

FIGURE 21.—Concluded. Rotating disk with hole. Inconel X; γ_0 , 0.3000.FIGURE 22.—Variation of load (function of speed) with ratio of inner to outer radius of rotating disk with hole. Inconel X; $\gamma_0=0.3000$.

in figure 22. The dashed curve in figure 22 is obtained by extending this solid curve toward $a/b=1$, where the value of $\rho(\omega b)^2$ can be determined by considering a rotating ring with $a/b \rightarrow 1$. The figure indicates approximately how the load $\rho(\omega b)^2$ varies with disks having different ratios of inner to outer radius and reaching the same maximum octahedral shear strain at the inner radius of the disk. The value of $\rho(\omega b)^2$ for a solid rotating disk made of Inconel X with $\gamma_0=0.3$ at the center of the disk is indicated in the same figure.

CONCLUSIONS

The results obtained for a membrane, a rotating disk without and with a hole, and an infinite plate with a hole strained in the strain-hardening range in which the elastic strains are negligible compared with the plastic strains for Inconel X and 16-25-6 in the absence of time and temperature effects and unloading show that:

(1) The method developed not only accurately solves the plane-plastic-stress problems with axial symmetry in a simple manner but also shows clearly the octahedral shear strain distribution and the ratio of principal stresses during loading.

(2) The ratio of the principal stresses in the cases investigated remained essentially constant during loading and, consequently, the deformation theory is applicable to this group of problems for the materials considered.

(3) The distributions of principal strains and octahedral shear strains in the plastic state are less uniform than those in the elastic state, although the distributions of tangential stresses appear more uniform in the plastic state. The stress concentration factor around a hole is reduced in the plastic state, but instead there is a high concentration of principal strain and octahedral shear strain.

(4) The ratios of the strains along the radius to their maximum value are essentially independent of the value of the maximum octahedral shear strain of the member and the octahedral shear stress-strain curve of the material. Hence, the deformation that can be sustained by the member before failure depends mainly on the maximum octahedral shear strain (or ductility) of the material.

(5) The stress distributions depend on the octahedral shear stress-strain curve of the material. Hence, the added load that the member can sustain between the onset of yielding and failure depends mainly upon the octahedral shear (or effective) stress-strain curve in the strain-hardening range of the material.

LEWIS FLIGHT PROPULSION LABORATORY

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS

CLEVELAND, OHIO, February 28, 1950

APPENDIX A

EQUATIONS OF EQUILIBRIUM AND COMPATIBILITY FOR INFINITESIMAL STRAIN IN TERMS OF α AND γ

The final forms of the equilibrium and compatibility equations for small strains are given in this section. The concept of infinitesimal strain is defined as follows: The changes of dimensions are small compared with the original dimensions but are large enough so that the elastic strain can be neglected. The equations presented can be obtained either by direct derivation as was done previously or by reducing the equations for finite strains through expanding the $e^{f(\alpha, \gamma)}$ terms in series and neglecting the small terms. For infinitesimal strain, the coefficients (functions of α and γ) A , B , C , D , E , and F of equations (25) are each denoted by a superscript prime but the coefficients (functions of α and γ) are simpler than those for large strain.

$$A' \frac{r}{k} \frac{d\alpha}{d\left(\frac{r}{k}\right)} + B' \frac{r}{k} \frac{d\gamma}{d\left(\frac{r}{k}\right)} = C' \quad (25a)$$

$$D' \frac{r}{k} \frac{d\alpha}{d\left(\frac{r}{k}\right)} + E' \frac{r}{k} \frac{d\gamma}{d\left(\frac{r}{k}\right)} = F'$$

For the circular membrane under pressure,

$$\left. \begin{aligned} A' &= \sqrt{3} \cos \alpha + \sin \alpha \\ B' &= (\sqrt{3} \sin \alpha - \cos \alpha) \frac{1}{\tau} \frac{d\tau}{d\gamma} \\ C' &= 2 \cos \alpha \\ D' &= (\sqrt{3} \sin \alpha - \cos \alpha) \gamma \\ E' &= -(\sqrt{3} \cos \alpha + \sin \alpha) \\ F' &= 2\sqrt{3} \gamma \cos \alpha + \frac{\sqrt{2}}{6} \left[\frac{\frac{pk}{h_{ini}} \frac{r}{k}}{\tau(\sqrt{3} \sin \alpha - \cos \alpha)} \right]^2 \end{aligned} \right\} \quad (36)$$

For the rotating disk,

$$\left. \begin{aligned} A' &= \sqrt{3} \cos \alpha + \sin \alpha \\ B' &= (\sqrt{3} \sin \alpha - \cos \alpha) \frac{1}{\tau} \frac{d\tau}{d\gamma} \\ C' &= 2 \cos \alpha - \sqrt{\frac{2}{3}} \rho(\omega k)^2 \left(\frac{r}{k}\right)^2 \frac{1}{\tau} \\ D' &= (\sqrt{3} \sin \alpha - \cos \alpha) \gamma \\ E' &= -(\sqrt{3} \cos \alpha + \sin \alpha) \\ F' &= 2\sqrt{3} (\cos \alpha) \gamma \end{aligned} \right\} \quad (37)$$

For the infinite plate with a circular hole,

$$\left. \begin{aligned} A' &= \sqrt{3} \cos \alpha + \sin \alpha \\ B' &= (\sqrt{3} \sin \alpha - \cos \alpha) \frac{1}{\tau} \frac{d\tau}{d\gamma} \\ C' &= 2 \cos \alpha \\ D' &= (\sqrt{3} \sin \alpha - \cos \alpha) \\ E' &= -(\sqrt{3} \cos \alpha + \sin \alpha) \\ F' &= 2\sqrt{3} (\cos \alpha) \gamma \end{aligned} \right\} \quad (38)$$

For small strains, the coefficients A' , B' , C' , D' , E' , and F' are used in equation (29) instead of A , B , C , D , E , and F ; respectively.

APPENDIX B

EQUATIONS FOR ROTATING DISK AND INFINITE PLATE
WITH CIRCULAR HOLE IN ELASTIC RANGE

ROTATING DISK

For a solid rotating disk with the radial stress at the periphery ($r=b$) equal to zero, the principal stresses can be expressed by the following equations (reference 23, p. 68):

$$\left. \begin{aligned} \sigma_r &= \frac{3+\nu}{8} \rho \omega^2 (b^2 - r^2) \\ \sigma_\theta &= \frac{3+\nu}{8} \rho \omega^2 b^2 - \frac{1+3\nu}{8} \rho \omega^2 r^2 \end{aligned} \right\} \quad (39)$$

where ν is Poisson's ratio. At $r=b$,

$$(\sigma_\theta)_b = \frac{1}{4} \rho \omega^2 b^2 (1-\nu)$$

Dividing equation (39) by $(\sigma_\theta)_b$ yields

$$\left. \begin{aligned} \frac{\sigma_r}{(\sigma_\theta)_b} &= \frac{3+\nu}{2(1-\nu)} \left[1 - \left(\frac{r}{b} \right)^2 \right] \\ \frac{\sigma_\theta}{(\sigma_\theta)_b} &= \frac{3+\nu}{2(1-\nu)} \left[1 - \frac{1+3\nu}{3+\nu} \left(\frac{r}{b} \right)^2 \right] \end{aligned} \right\} \quad (39a)$$

The stress-strain relations of plane-stress problems in the elastic range are:

$$\left. \begin{aligned} \epsilon_r &= \frac{1}{E} (\sigma_r - \nu \sigma_\theta) \\ \epsilon_\theta &= \frac{1}{E} (\sigma_\theta - \nu \sigma_r) \end{aligned} \right\} \quad (40)$$

where E is the modulus of elasticity in tension and compression.

Substituting equations (39) into equations (40) yields:

$$\left. \begin{aligned} \epsilon_r &= \frac{1}{8E} (1-\nu)(3+\nu)(\rho \omega^2 b^2) \left[1 - \frac{3(1+\nu)}{3+\nu} \left(\frac{r}{b} \right)^2 \right] \\ \epsilon_\theta &= \frac{1}{8E} (1-\nu)(3+\nu)(\rho \omega^2 b^2) \left[1 - \frac{1+\nu}{3+\nu} \left(\frac{r}{b} \right)^2 \right] \end{aligned} \right\} \quad (40a)$$

or

$$\left. \begin{aligned} \frac{\epsilon_r}{(\epsilon_\theta)_b} &= \frac{3+\nu}{2} \left[1 - \frac{3(1+\nu)}{3+\nu} \left(\frac{r}{b} \right)^2 \right] \\ \frac{\epsilon_\theta}{(\epsilon_\theta)_b} &= \frac{3+\nu}{2} \left[1 - \frac{1+\nu}{3+\nu} \left(\frac{r}{b} \right)^2 \right] \end{aligned} \right\} \quad (40b)$$

The equations for the octahedral shear stress and strain given by equations (4a), (4b), and (5a) can be applied to both the elastic and the plastic ranges, but equation (5b) can be applied only in the plastic range. The octahedral shear strain in the elastic range can be calculated by equation (4b) or by using the following equation:

$$\gamma = \frac{2(1+\nu)}{E} \tau = \frac{2(1+\nu)}{E} \frac{\sqrt{2}}{3} (\sigma_r^2 - \sigma_r \sigma_\theta + \sigma_\theta^2)^{1/2} \quad (41)$$

Substitute equations (39) in equation (41) to obtain:

$$\gamma = \frac{\sqrt{2}}{12E} \frac{(1+\nu)}{(3+\nu)} (\rho \omega^2 b^2) \left[(3+\nu)^2 - 4(1+\nu)(3+\nu) \left(\frac{r}{b} \right)^2 + (7+2\nu+7\nu^2) \left(\frac{r}{b} \right)^4 \right]^{1/2} \quad (41a)$$

or

$$\frac{\gamma}{\gamma_b} = \frac{1}{2(1-\nu)} \left[(3+\nu)^2 - 4(1+\nu)(3+\nu) \left(\frac{r}{b} \right)^2 + (7+2\nu+7\nu^2) \left(\frac{r}{b} \right)^4 \right]^{1/2} \quad (41b)$$

The value of Poisson's ratio ν for the two materials are:

$$\nu = 0.29 \text{ for Inconel X (reference 24)}$$

$$\nu = 0.286 \text{ for 16-25-6 (reference 25)}$$

INFINITE PLATE WITH CIRCULAR HOLE

For a uniformly loaded infinite plate with a circular hole, the principal stresses are (reference 23, p. 56):

$$\left. \begin{aligned} \sigma_r &= \frac{A}{r^2} + 2C \\ \sigma_\theta &= -\frac{A}{r^2} + 2C \end{aligned} \right\} \quad (42)$$

where A and C are arbitrary constants. For the plate considered herein, the boundary conditions are:

$$\begin{aligned} \sigma_r &= 0 & \text{at } r=a \\ \sigma_r &= (\sigma_r)_b & \text{at } r=b \end{aligned}$$

These boundary conditions are used to determine the arbitrary constants A and C , which yield

$$\left. \begin{aligned} \sigma_r &= \frac{(\sigma_r)_b}{1 - \left(\frac{a}{b} \right)^2} \frac{\left(\frac{r}{a} \right)^2 - 1}{\left(\frac{r}{a} \right)^2} \\ \sigma_\theta &= \frac{(\sigma_r)_b}{1 - \left(\frac{a}{b} \right)^2} \frac{\left(\frac{r}{a} \right)^2 + 1}{\left(\frac{r}{a} \right)^2} \end{aligned} \right\} \quad (42a)$$

or

$$\left. \begin{aligned} \frac{\sigma_r}{(\sigma_\theta)_b} &= \frac{1}{1 + \left(\frac{a}{b} \right)^2} \frac{\left(\frac{r}{a} \right)^2 - 1}{\left(\frac{r}{a} \right)^2} \\ \frac{\sigma_\theta}{(\sigma_\theta)_b} &= \frac{1}{1 + \left(\frac{a}{b} \right)^2} \frac{\left(\frac{r}{a} \right)^2 + 1}{\left(\frac{r}{a} \right)^2} \end{aligned} \right\} \quad (42b)$$

Substituting equations (42a) into equations (40) yields

$$\left. \begin{aligned} \epsilon_r &= \frac{1}{E} \frac{(\sigma_r)_b}{1 - \left(\frac{a}{b}\right)^2} \frac{(1-\nu)\left(\frac{r}{a}\right)^2 - (1+\nu)}{\left(\frac{r}{a}\right)^2} \\ \epsilon_\theta &= \frac{1}{E} \frac{(\sigma_r)_b}{1 - \left(\frac{a}{b}\right)^2} \frac{(1-\nu)\left(\frac{r}{a}\right)^2 + (1+\nu)}{\left(\frac{r}{a}\right)^2} \end{aligned} \right\} \quad (43)$$

or

$$\left. \begin{aligned} \frac{\epsilon_r}{(\epsilon_\theta)_b} &= \frac{(1-\nu)\left(\frac{r}{a}\right)^2 - (1+\nu)}{\left[(1-\nu) + (1+\nu)\left(\frac{a}{b}\right)^2\right]\left(\frac{r}{a}\right)^2} \\ \frac{\epsilon_\theta}{(\epsilon_\theta)_b} &= \frac{(1-\nu)\left(\frac{r}{a}\right)^2 + (1+\nu)}{\left[(1-\nu) + (1+\nu)\left(\frac{a}{b}\right)^2\right]\left(\frac{r}{a}\right)^2} \end{aligned} \right\} \quad (43a)$$

Substituting equations (42a) into equation (41) yields

$$\gamma = \frac{2\sqrt{2}(1+\nu)}{3E} \frac{(\sigma_r)_b}{1 - \left(\frac{a}{b}\right)^2} \left[\frac{\left(\frac{r}{a}\right)^4 + 3}{\left(\frac{r}{a}\right)^4} \right]^{1/2} \quad (44)$$

or

$$\frac{\gamma}{\gamma_b} = \left\{ \frac{\left(\frac{r}{a}\right)^4 + 3}{\left[1 + 3\left(\frac{a}{b}\right)^4\right]\left(\frac{r}{a}\right)^4} \right\}^{1/2}$$

REPORT 1022

TEMPERATURE DISTRIBUTION IN INTERNALLY HEATED WALLS OF HEAT EXCHANGERS COMPOSED OF NONCIRCULAR FLOW PASSAGES¹

By E. R. G. ECKERT and GEORGE M. LOW

SUMMARY

In the walls of heat exchangers composed of noncircular passages, the temperature varies in the circumferential direction because of local variations of the heat-transfer coefficients. A prediction of the magnitude of this variation is necessary in order to determine the region of highest temperature and in order to determine the admissible operating temperatures.

A method for the determination of these temperature distributions and of the heat-transfer characteristics of a special type of heat exchanger is developed. The heat exchanger is composed of polygonal flow passages and the passage walls are uniformly heated by internal heat sources. The coolant flow within the passages is assumed to be turbulent. The circumferential variation of the local heat-transfer coefficients is estimated from flow measurements made by Nikuradse, postulating similarity between velocity and temperature fields. Calculations of temperature distributions based on these heat-transfer coefficients are carried out and results for heat exchangers with triangular and rectangular passages are presented.

INTRODUCTION

The conventional recuperative type of heat exchanger consists of passages for two liquids or gases separated by a heating surface. Heat from an outside source is carried with a fluid flowing through one of the passages and is transferred in the heat exchanger to a second fluid flowing through the other passage. Very often such a heat exchanger is composed of a large number of tubes, with the two liquids flowing inside and over the outside of the tubes, respectively.

The regenerative type of heat exchanger has passages for one fluid only. During the heating period, heat from an outside source is carried to the heat exchanger by a hot fluid and is stored within the solid walls of the passages. This heat is then given off to a cold fluid, which passes through the heat exchanger during the cooling period.

In this report, a heat exchanger is considered that differs from the regenerative type only by the fact that the heat is generated by heat sources within the passage walls and is transferred to a coolant flowing continuously through the passages. The passage walls of this heat exchanger are assumed to be flat plates assembled to form a honeycomb; thus the flow passages formed in this manner have a polygonal cross section. A cross-sectional view of a typical heat

exchanger of this type is shown in figure 1. The exchanger is composed of a number of plates *a*, which form the coolant passages *b*. The flow of the coolant is normal to the cross section shown. High temperatures may be anticipated near the corners *c* of the passages, inasmuch as the rate of heat transfer there is expected to be poor. A theoretical investigation of the temperature distribution in such a heat exchanger was made at the NACA Lewis laboratory during 1950 and is presented herein.

The basis for this investigation is a knowledge of local heat-transfer coefficients in passages of noncircular cross section. Some information is available on the average heat-transfer coefficients in such tubes (references 1 and 2). The result of these investigations is essentially that the expressions derived for the heat-transfer coefficients in circular tubes apply for other cross sections as well, provided the diameter is replaced by the hydraulic diameter. (The hydraulic diameter is defined as four times the cross-sectional flow area divided by the circumference of the passage.)

A knowledge of local heat-transfer coefficients in noncircular passages is important not only in the present problem, but also for several other engineering problems, such as the determination of local temperatures in the walls of air-cooled turbine blades. No information on local heat-transfer coefficients was found in the available literature, however. These values are therefore estimated from flow measurements made by Nikuradse (reference 3) on the basis of the similarity between temperature and velocity fields.

SYMBOLS

The following symbols are used in this report:

A	cross-sectional flow area (sq ft)
A^*	ratio of wall area to flow area (dimensionless)
C	internal circumference of passage (ft)
C^*	C/D (dimensionless)
c_p	specific heat at constant pressure, Btu/(lb) (°F)
D	hydraulic diameter, $4A/C$, (ft)
g	acceleration due to gravity (ft)/(sec ²)
h	local heat-transfer coefficient, Btu/(sec) (sq ft) (°F)
$\bar{h}$	average heat-transfer coefficient, $\frac{1}{C} \int_0^C h \, dx$, Btu/(sec) (sq ft) (°F)
h^*	$\bar{h}/h$ (dimensionless)
k	thermal conductivity of wall material, Btu/(sec) (ft) (°F)
k_g	thermal conductivity of coolant, Btu/(sec) (ft) (°F)
k^*	k/k_g (dimensionless)
N	residual value (dimensionless)
Nu	Nusselt number, $\bar{h}D/k_g$, (dimensionless)
n	coordinate normal to passage wall (ft)
n^*	n/D (dimensionless)
Pr	Prandtl number, ν/α , (dimensionless)
p	pressure (lb)/(sq ft)
q	local rate of heat transfer, $h\theta$, Btu/(sec) (sq ft)
q^*	$h^* \theta^*$ (dimensionless)
R	radial coordinate (ft)
Re	Reynolds number, uD/ν , (dimensionless)
r	rate of internal heat generation, Btu/(sec) (cu ft)
s	wall thickness (ft)
s^*	s/D (dimensionless)
T	local total temperature of coolant, °F
T_B	bulk total temperature of coolant, °F
T^*	Tk/rD^2 (dimensionless)
t	local wall temperature, °F
t^*	tk/rD^2 (dimensionless)
u, v	velocity components in x - and y -direction, respectively (ft/sec)
x, y, z	Cartesian coordinates
x^*	x/D (dimensionless)
y^*	y/D (dimensionless)
z^*	z/D (dimensionless)
α	thermal diffusivity, $k_g/\rho g c_p$, (sq ft)/(sec)
β	angle subtended by two adjacent sides of polygonal passage (deg)
Δ	increment of length (ft)
Δ^*	Δ/D (dimensionless)
δ	increment or difference
ϵ_H	turbulent diffusivity of heat (sq ft)/(sec)
ϵ_M	turbulent diffusivity of momentum (sq ft)/(sec)
θ	temperature difference, $t - T_B$, °F
θ^*	$\theta k/rD^2$ (dimensionless)
ν	kinematic viscosity (sq ft)/(sec)
ρ	mass density (lb) (sec ²)/(ft ⁴)
τ_w	local wall shear stress (lb)/(sq ft)

Subscripts:

c	conditions for equivalent circular tube
m	conditions at center of flow passage
n	conditions normal to passage wall
s	conditions at wall surface

Superscript:

$*$	dimensionless quantity
-----	------------------------

ASSUMPTIONS

If this analysis were to be made without any simplifying assumptions, the simultaneous solution of the equations of motion of the coolant and of the heat flow in the coolant and in the passage walls would be required. The following assumptions are made in order to make these equations amenable to solution without seriously curtailing the results of the analysis:

(1) The Prandtl number of the coolant used in the heat exchanger is in the neighborhood of 1. This condition is well fulfilled by gases and by water above a temperature of 200° F, excluding the neighborhood of the critical point.

(2) The passages of the heat exchanger are long enough so that in the cross section investigated the flow is fully developed, which means that the velocity profile does not change its shape in the direction of the tube axis.

(3) The rate of heat generation in the walls of the heat exchanger is uniform. As a consequence of this condition, the temperature within the coolant and the walls increases linearly in a downstream direction provided the flow is thermally developed. For a fluid with a Prandtl number of 1, the points of thermal and velocity development in a tube practically coincide provided that the heating of the tube starts at the entrance section.

(4) The temperature gradient along the tube axis is assumed small as compared with the gradients in any cross section of the passage.

(5) The thermal conductivity of the solid material is large as compared with the thermal conductivity of the coolant. This condition is always fulfilled for metal walls regardless of the type of coolant used provided that assumption (1) applies and for nonmetallic walls if the coolant is a gas. For the case of nonmetallic walls and liquid coolants, the applicability of the calculations presented in this report must be checked in each individual case. Furthermore, the temperature differences within the passage wall at any one cross section are postulated to be small as compared with the temperature differences between the wall and the core of the coolant. As a consequence of the assumption listed in this paragraph, the heat transport within the coolant, normal to the tube axis and parallel to the walls, is small as compared with the heat conduction within the walls and may therefore be neglected. The heat transport within the coolant, normal to the tube axis and normal to the walls, is of course taken into account.

(6) The turbulent diffusivity of momentum ϵ_M and that of heat ϵ_H are equal.

FLOW IN TUBES WITH NONCIRCULAR CROSS SECTION

A thorough investigation of the flow through tubes with noncircular cross sections was made by Nikuradse (reference 3). This investigation is used in the present report as the basis for estimating local heat-transfer coefficients.

The flow of water through tubes of several different shapes, as shown in figure 2, was investigated in reference 3. Three of the tubes had triangular cross sections; an equilateral triangle, an isosceles right triangle, and a right triangle with the sides enclosing the 90° angle having a ratio of 1 to 2.32. One tube had a trapezoidal cross section and two tubes were circular with one and two grooves, respectively. In a second report, Nikuradse investigated tubes with a rectangular cross section; however, only a summary of this report is available (reference 4). The hydraulic diameter of the passages varied from 0.3 to 0.6 inch and the length-to-hydraulic-diameter ratio varied from 100 to 200. The Reynolds number based on the hydraulic diameter and the mean velocity ranged from 77,000 to 120,000. Because it is known that the shape of a turbulent velocity profile changes only slightly with Reynolds number, the results of the calculations should be applicable for a fairly large range of Reynolds number in the turbulent region. The velocity profiles were measured

FIGURE 2.—Cross sections of passages investigated in reference 3.

FIGURE 3.—Velocity contours in triangular passage as measured in reference 3. Reynolds number, 81,000.

with a small total-head tube in a cross section near the downstream end of the tube.

Results of reference 3 for the isosceles right triangle are shown in figures 3 to 5. Similar results for all other cross

FIGURE 4.—Secondary flow in triangular passage deduced from measurements of reference 3.

FIGURE 5.—Shear stress distribution on circumference of triangular passage as determined in reference 3.

sections can be found in the original report. In figure 3 the lines of constant velocity are presented as contour lines. These contours are indented near the center of each side of the passage. The conclusion of reference 3 is that these indentations indicate a secondary flow normal to the main flow direction. A qualitative sketch of this secondary flow is presented in figure 4. Prandtl (reference 5) has ascribed the secondary flow to a turbulent mixing motion within the fluid, which is more intense in the direction parallel to the wall than normal to it. This secondary flow tends to equalize the velocities and temperatures within any cross section of a noncircular tube and is therefore favorable for the similarity consideration that will be used to deduce the temperature field from the measured velocity field. On the other hand, because no quantitative knowledge of the secondary flow exists, an exact theoretical calculation of the temperature field in noncircular passages is impossible. The local wall shear stresses were computed by Nikuradse, using the measured velocity profiles together with the assumption that the Blasius pipe resistance law of the turbulent velocity profile for circular tubes applies also for noncircular passages on normals to the walls (fig. 5). A check by Nikuradse of the calculated average shear stresses against the measured pressure drop showed good agreement.

SIMILARITY BETWEEN VELOCITY AND TEMPERATURE PROFILES FOR $Pr=1$

It is well known that the velocity and temperature profiles in the boundary layer of a fluid with a Prandtl number of 1 are similar in shape in the absence of a pressure gradient. This similarity is immediately apparent from a comparison of the momentum and energy equations of the boundary layer for two-dimensional steady flow along a flat plate (reference 6):

$$\rho \left(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) = \frac{\partial}{\partial y} \left[\rho (\nu + \epsilon_M) \frac{\partial u}{\partial y} \right] \quad (1)$$

$$\rho \left(u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} \right) = \frac{\partial}{\partial y} \left[\rho (\nu + \epsilon_H) \frac{\partial T}{\partial y} \right] \quad (2)$$

where T represents the total temperature, the Prandtl number is equal to 1, and the specific heat is constant. The effect of internal friction on the temperature profile is taken into account by basing equation (2) on the total temperature.

Because it is assumed that the turbulent diffusivity of momentum ϵ_M and of heat ϵ_H are equal, equations (1) and (2) are similar. The solutions of the equations, namely, the velocity and temperature profiles, are therefore also similar, provided the boundary conditions are similar. The boundary conditions for the velocity field on a flat plate are that the velocity is 0 along the wall and has a constant value outside the boundary layer. Similar boundary conditions for the temperature field are that the temperature is constant both along the wall and in the main stream.

It is therefore evident that similarity between velocity and temperature profiles in the boundary layer over a flat

plate exists in an exact mathematical sense. The same is not true, however, for fully developed pipe flow. The balance of the forces and of the heat energy on a stationary annular volume element with a radius R , thickness dR , and length (in the direction of the tube axis) dz , leads to the following equations for fully developed flow in a circular tube:

$$\frac{1}{R} \frac{\partial}{\partial R} \left[R \rho (\nu + \epsilon_M) \frac{\partial u}{\partial R} \right] = \frac{dp}{dz} \quad (3)$$

$$\frac{1}{R} \frac{\partial}{\partial R} \left[R \rho (\alpha + \epsilon_H) \frac{\partial T}{\partial R} \right] = \rho u \frac{\partial T}{\partial z} \quad (4)$$

where the heat-conduction term in the z -direction is neglected in equation (4). It is apparent that equations (3) and (4) are not similar, even if the viscosity and diffusivity terms in the two equations are equal. The following type of analysis can be made, however:

The turbulent diffusivity of momentum ϵ_M can be calculated from equation (3), provided that the velocity profile $u=f(R)$ and the pressure drop dp/dz are experimentally known. If it is again assumed that ϵ_M and ϵ_H are equal, the temperature profile can then be calculated from equation (4). Such an analysis, based on constant property values and with internal friction neglected, was carried out by Latzko (reference 7). The results of this analysis were used to calculate the relation between the temperatures and the velocities for hydrodynamically and thermally developed flow of a fluid with $Pr=1$. Figure 6 represents a plot of the local temperature-difference ratio $(T-t_s)/(T_m-t_s)$ against the local velocity ratio u/u_m . It can be seen that this relation is very nearly linear. This linearity means that the velocity and temperature profiles are similar as far as practicality is con-

FIGURE 6.—Relation between local temperatures and local velocities in fully developed turbulent region of circular tube. Based on reference 7.

FIGURE 7. Local heat-transfer coefficients in corners of noncircular passages.

cerned, even though they are not similar in a strict mathematical sense. Most of the recent theoretical investigations of turbulent heat transfer are therefore based on the assumption of similarity between these profiles for a fluid with a Prandtl number of 1.

It is known that the fully developed turbulent velocity profile in a circular tube is such that the essential part of the velocity change from 0 at the wall to a maximum value at the center occurs in a narrow strip around the periphery of the tube. The investigations of references 3 and 4 show that this condition is also true for tubes of polygonal cross section, as long as the included angles between two adjacent passage walls are not very small. Nikuradse further shows that the law for the velocity variation on a normal to the wall established for turbulent flow in circular tubes holds also for the noncircular passages in this region of essential velocity variation. It can therefore be expected that the similarity between temperature and velocity profiles will also be fulfilled reasonably well on normals to the walls for noncircular tubes and fluids with a Prandtl number of 1, although a balance of forces and energies similar to equations (3) and (4) shows that the similarity cannot exist exactly in regions very close to the corners.

An immediate result of the similarity between velocity and temperature profiles is the fact that the local wall shear stress determined by the velocity gradient at the wall is proportional to the local heat-transfer coefficient determined by the temperature gradient at the wall. (The same result can be

obtained from Reynolds' analogy.) The proportionality of these values, together with the knowledge that the average heat-transfer coefficients for circular and noncircular tubes with the same hydraulic diameter are equal, can be used to obtain local heat-transfer coefficients in noncircular tubes from the wall-shear-stress data of references 3 and 4. A generalization of this result is possible because, for a given Reynolds number, the shear stress distribution in the vicinity of a corner of the passage depends primarily on the conditions near that corner and not on the shape of the passage.

The local heat-transfer coefficients, as presented in figure 7, were obtained by correlating the results of references 3 and 4. In this figure the ratio h^* of the local heat-transfer coefficient to the mean value is plotted against the dimensionless distance from the corner x^* . The included angle of two adjacent passage walls is the parameter for the curves. Some of these corner angles were represented on more than one of the cross sections investigated in reference 3, and for these angles the curves of h^* against x^* agree reasonably well.

The application of figure 7 can best be explained with the aid of an example. Suppose it is desired to find the distribution of h^* over the short leg of an isosceles right triangle, as shown in figure 8. The two ends of the curve can immediately be transposed from figure 7. The remainder of the curve is then extrapolated so that the area under the curve divided by length $\overline{AB}$ is equal to 1. This procedure gives a reasonably good approximation as long as the maximum value of h^* is not considerably greater than 1.

DIMENSIONLESS VARIABLES

With the distribution of the local heat-transfer coefficient around the circumference of the passages established, the only problem remaining to be solved is the calculation of the heat-conduction process within the passage walls. Before this problem is taken up, an investigation is made to determine the dimensionless moduli on which the temperature distribution in a heat exchanger of the type under consideration depends. This investigation may be useful as a basis for experimental investigations. None of the simplifying assumptions, as summarized previously, is necessary for the development in this section of the report.

The heat conduction within the solid walls of a heat exchanger with internal heat generation is described by Poisson's equation

$$k\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial z^2}\right) + r = 0 \quad (5)$$

The number of parameters for this equation can be reduced by the use of the following dimensionless values:

$$t^* = \frac{tk}{rD^2} \quad x^* = \frac{x}{D} \quad y^* = \frac{y}{D} \quad z^* = \frac{z}{D} \quad (6)$$

With these values, equation (5) can be rewritten

$$\frac{\partial^2 t^*}{\partial x^{*2}} + \frac{\partial^2 t^*}{\partial y^{*2}} + \frac{\partial^2 t^*}{\partial z^{*2}} + 1 = 0 \quad (7)$$

The temperature field that results under the influence of the internal heat generation in the solid walls depends on how the heat is transferred from the wall surfaces to the coolant. The heat must be conducted within the solid material to the surface and from there into the coolant. Along the surface, therefore, the following boundary condition exists:

$$k\left(\frac{\partial t}{\partial n}\right)_s = k_s\left(\frac{\partial T}{\partial n}\right)_s \quad (8)$$

where n represents the direction normal to the surface. In terms of dimensionless variables, this equation becomes

$$k^*\left(\frac{\partial t^*}{\partial n^*}\right)_s = \left(\frac{\partial T^*}{\partial n^*}\right)_s \quad (9)$$

FIGURE 8.—Determination of local heat-transfer coefficients in triangular heat-exchanger passage.

The heat transfer within the coolant by conduction and convection is governed by an energy equation similar to equation (4) and the flow of the coolant is determined by a momentum equation (similar to equation (3)) and the corresponding continuity equation. Textbooks on heat transfer (for example, reference 8) show that the dimensionless temperature described by the energy equation of the coolant depends, for low-velocity flow and constant property values, on the Reynolds number Re and the Prandtl number Pr . At high velocities and variable property values, there is an additional influence of the Mach number and other dimensionless expressions characterizing the temperature dependency on the property values. By neglecting the last-mentioned influences and summarizing all the factors that influence the heat flow in the solid material and in the coolant, a functional relation of the following type can be deduced:

$$\theta^* = f(Re, Pr, k^*, x^*, y^*, z^*) \quad (10)$$

where the temperature difference θ^* is introduced because only temperature differentials appear in the equations. The function f as expressed by this equation depends on the geometric configuration of the heat-exchanger passages.

When it can be assumed that the heat-transfer process from the walls to the coolant is not influenced by the temperature distribution within the wall, the number of factors influencing the problem can be considerably reduced. This assumption is made throughout the calculations in this report and seems reasonable as long as previously mentioned assumption (5) holds. In this case equation (8) can be replaced by

$$k\left(\frac{\partial t}{\partial n}\right)_s = -h(t_s - T_B) \quad (11)$$

where h is a known function of the flow parameters. By introducing the ratio h^* of the local heat-transfer coefficient to the value averaged over the circumference of the passage and the Nusselt number $Nu = \bar{h}D/k_g$ based on this average value, and by changing to the temperature difference θ , equation (11) can be transformed to

$$\left(\frac{\partial \theta^*}{\partial n^*}\right)_s = -Nu \frac{h^*}{k^*} \theta_s^* \quad (12)$$

The dimensionless temperature within the solid walls of the heat exchanger is determined by equations (7) and (12) and can be presented as a function of the following kind:

$$\theta^* = f\left(Nu \frac{h^*}{k^*}, x^*, y^*, z^*\right) \quad (13)$$

This dimensionless temperature difference depends only on the dimensionless local coordinates and on the parameter $Nu \frac{h^*}{k^*}$. Temperature distributions and heat-transfer characteristics for any given geometric configuration are therefore presented as a one-parameter family of curves.

CALCULATION OF TEMPERATURE DISTRIBUTIONS WITHIN PASSAGE WALLS

The problem of calculating temperature distributions within the passage walls can be classified in two general categories, depending on the relative thickness of these walls. If the dimensionless wall thickness s^* (see fig. 8) is small as compared with the length of a wall $\overline{AB}$, the temperature differences in the direction normal to the wall surface are small as compared with the temperature difference in the direction x^* parallel to the surface. Only the temperature differences in this parallel direction need therefore be considered. Hereinafter this special case of the problem is referred to as the "one-dimensional problem." On the other hand, if s^* becomes large, the heat flow in both the x^* and s^* directions must be considered. This second and more general problem is referred to as the "two-dimensional problem."

One-dimensional problem.—Consider a thin plate of thickness s that is a section of the heat-exchanger passage walls. Heat is generated uniformly throughout the plate at a rate r . The local plate (or wall) temperature t is assumed to be varying in the x -direction only. The bulk temperature of the coolant is T_B and the thermal conductivities of the wall and coolant are k and k_g , respectively. The local coefficients of heat transfer to the coolant above and below the plate are denoted by h and h' , as shown in the following sketch:

The heat balance for an element of volume with the dimensions dx and s and of unit depth is

$$Q + Q_i = Q' + Q_a + Q_a' \quad (14)$$

where

$$Q = -ks \frac{dt}{dx}$$

$$Q' = -ks \left(\frac{dt}{dx} + \frac{d^2t}{dx^2} dx \right)$$

$$Q_i = rs dx$$

$$Q_a + Q_a' = (h + h')(t - T_B) dx$$

With the preceding values of Q , equation (14) becomes

$$\frac{d^2t}{dx^2} - \frac{h + h'}{ks} (t - T_B) + \frac{r}{k} = 0 \quad (15)$$

Equation (15) can be expressed in terms of dimensionless variables as

$$\frac{d^2\theta^*}{dx^{*2}} - \frac{h^* + h'^*}{s^*k^*} Nu \theta^* + 1 = 0 \quad (16)$$

This equation expresses the dimensionless wall temperature θ^* as a function of the dimensionless coordinate x^* and a single parameter $(h^* + h'^*)Nu/s^*k^*$. For any given geometric configuration (which determines h^* and h'^* as functions of x^*), the dimensionless wall temperature is a function only of the average Nusselt number Nu , the dimensionless wall thickness s^* , and the ratio of the thermal conductivities k^* .

In general, equation (16) must be solved by numerical means inasmuch as h^* and h'^* are experimentally determined functions of x^* . Several numerical methods of solution can be applied and two of these are considered here. The relaxation method (see, for example, reference 2, pp. 365-379, or reference 9) has the advantage that it is easy to apply and that computational errors are immediately apparent. A second method of solution, based on the Runge-Kutta method (reference 10) is presented in the appendix. This method is preferable when results of high accuracy are desired. It is less convenient, however, than the relaxation method because computational errors are much more difficult to detect.

For the purpose of solving equation (16) by the relaxation method, the equation is first expressed in finite-difference form. Consider a grid, or net of points, placed into the wall, any two adjacent points being separated by a small but finite distance Δ^* , as indicated in the following sketch:

The second derivative of θ^* at an arbitrary point 0 can be expressed in terms of the temperatures θ^* at this point and the two adjacent points as follows:

$$\begin{aligned} \left(\frac{d\theta^*}{dx^*} \right)_0 &\approx \frac{\theta_1^* - \theta_0^*}{\Delta^*} & \left(\frac{d\theta^*}{dx^*} \right)_2 &\approx \frac{\theta_0^* - \theta_2^*}{\Delta^*} \\ \frac{d^2\theta^*}{dx^{*2}} &\approx \frac{1}{\Delta^{*2}} \left[\left(\frac{d\theta^*}{dx^*} \right)_0 - \left(\frac{d\theta^*}{dx^*} \right)_2 \right] \\ &\approx \frac{1}{\Delta^{*2}} (\theta_1^* + \theta_2^* - 2\theta_0^*) \end{aligned} \quad (17)$$

With this value for the second derivative, equation (16) becomes

$$\theta_1^* + \theta_2^* - \theta_0^* \left[2 + \frac{Nu}{s^*k^*} (h^* + h'^*)_0 \Delta^{*2} \right] + \Delta^{*2} = 0 \quad (18)$$

The relaxation method, used for solving this equation, is subsequently discussed.

Two-dimensional problem.—Consider a slab of homogeneous solid material with unit thickness, as shown in the following diagram:

Heat is again generated within the material at a uniform rate r . The heat balance for an element of volume with the dimensions dx and dy and of unit depth is

$$Q_x + Q_y + Q_i = Q_x' + Q_y' \quad (19)$$

A constant flow of heat through the slab normal to the plane of the preceding sketch does not influence this heat balance. Local deviations from this constant flow of heat are neglected.

The individual terms in equation (19) are

$$\begin{aligned} Q_x &= -k dy \frac{\partial t}{\partial x} \\ Q_x' &= -k dy \left(\frac{\partial t}{\partial x} + \frac{\partial^2 t}{\partial x^2} dx \right) \\ Q_y &= -k dx \frac{\partial t}{\partial y} \\ Q_y' &= -k dx \left(\frac{\partial t}{\partial y} + \frac{\partial^2 t}{\partial y^2} dy \right) \\ Q_i &= r dx dy \end{aligned}$$

Equation (19) can therefore be written

$$\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} = -\frac{r}{k} \quad (20)$$

Or, in terms of the dimensionless variables,

$$\frac{\partial^2 \theta^*}{\partial x^{*2}} + \frac{\partial^2 \theta^*}{\partial y^{*2}} = -1 \quad (21)$$

If the slab is bounded by a coolant whose bulk temperature is T_B and if the local surface heat-transfer coefficient at a point s on the surface is h , the boundary condition at that point is

$$k \left(\frac{\partial t}{\partial n} \right)_s = -h(t - T_B)_s \quad (22)$$

where n is the direction normal to the surface. Equation (22) can again be written in terms of the dimensionless variables

$$\left(\frac{\partial \theta^*}{\partial n^*} \right)_s = -\frac{Nu h^*}{k^*} \theta_s^* \quad (23)$$

Equation (21) together with boundary condition (23) fully describes the two-dimensional problem. All physical variables are again grouped into a single parameter $h^* Nu/k^*$, which appears in the boundary condition. In order to apply the relaxation method of solution to these expressions, they are first converted to difference equations.

For this purpose a rectangular grid is placed into the slab, as indicated in the following diagram:

Adjacent net points are separated by a distance Δ^* . The derivatives of θ^* at an arbitrary point 0 can be expressed in terms of the temperature function at surrounding points. Thus the first derivatives are

$$\begin{aligned} \left(\frac{\partial \theta^*}{\partial x^*} \right)_0 &\approx \frac{\theta_1^* - \theta_0^*}{\Delta^*} & \left(\frac{\partial \theta^*}{\partial x^*} \right)_3 &\approx \frac{\theta_0^* - \theta_3^*}{\Delta^*} \\ \left(\frac{\partial \theta^*}{\partial y^*} \right)_0 &\approx \frac{\theta_2^* - \theta_0^*}{\Delta^*} & \left(\frac{\partial \theta^*}{\partial y^*} \right)_4 &\approx \frac{\theta_0^* - \theta_4^*}{\Delta^*} \end{aligned}$$

and the second derivatives become

$$\begin{aligned} \frac{\partial^2 \theta^*}{\partial x^{*2}} &\approx \frac{\theta_1^* + \theta_3^* - 2\theta_0^*}{\Delta^{*2}} \\ \frac{\partial^2 \theta^*}{\partial y^{*2}} &\approx \frac{\theta_2^* + \theta_4^* - 2\theta_0^*}{\Delta^{*2}} \end{aligned}$$

With these values, equation (21) becomes

$$\theta_1^* + \theta_2^* + \theta_3^* + \theta_4^* - 4\theta_0^* + \Delta^{*2} = 0 \quad (24)$$

The boundary condition can be evaluated by assuming that points 1, 0, and 3 lie on the surface of the wall. Point 4 then lies in the stream and its temperature must be expressed by the normal derivative at point 0.

$$\left(\frac{\partial \theta^*}{\partial y^*} \right)_0 \approx \frac{\theta_4^* - \theta_0^*}{\Delta^*}$$

or, with the use of the value of $\partial\theta^*/\partial y^*$ as given by equation (23),

$$\theta_4^* = \theta_0^* \left(1 - \frac{Nu h^*}{k^*} \Delta^* \right) \quad (25)$$

Along the boundary, therefore, the following equation applies:

$$\theta_1^* + \theta_2^* + \theta_3^* - \theta_0^* \left(3 + \frac{Nu h^*}{k^*} \Delta^* \right) + \Delta^{*2} = 0 \quad (26)$$

Equation (24) together with boundary condition (26) can again be solved by means of the relaxation method.

Solution by relaxation method.—A heat exchanger composed of a large number of rectangular passages will be discussed. The walls of the heat exchanger are made of a homogeneous material in which heat is generated at a uniform rate r . Figure 9 represents a cut through the heat exchanger so that the flow of coolant is in a direction normal to the cut. In the discussion that follows, it is assumed that the geometry of the configuration is given in the dimensionless system of coordinates.

A complete discussion of the relaxation method is not presented herein, inasmuch as it is generally available elsewhere. (See, for example, reference 9.) The essential features of the method can be outlined as follows:

Suppose it is desired to solve a given finite-difference equation over a certain area of integration. The equation is of the following type:

$$f(\theta^*) = 0 \quad (29)$$

The solution of equation (29) must also satisfy prescribed conditions at the boundary of the area of integration.

First, it is necessary to select a number of net points covering the entire area of integration. The distance Δ^* between net points is arbitrary, with the accuracy of the final solution increasing as the distance between points is decreased. Next, values of θ^* are assumed at each net point. If by chance these assumed values of θ^* are the correct values, then they satisfy the appropriate finite-difference equation at all net points.

In general, however, the assumed values of the function do not satisfy the difference equation and the left side of equation (29) is equal to some residual value N instead of zero. At any given net point θ^* must then be adjusted in order to make N vanish at that point. This adjustment of θ^* also changes the residuals at adjacent net points. However, if this process of adjustment is started at the point at which the absolute value of N is greatest and is then repeated for points at which the value of the residual is successively less, the correct values of θ^* for the entire net eventually are obtained.

In applying this method to the heat exchanger under consideration, it is first assumed that the wall thickness s^* is small, so that the one-dimensional solution applies.

FIGURE 9.—Thick-walled heat exchanger with rectangular passages. (Shaded region is considered in calculations.)

FIGURE 10.—Thin-walled heat exchanger with rectangular passages. (Calculation is confined to region ABC.)

FIGURE 11.—Relaxation net for rectangular thin-walled heat exchanger.

The actual configuration to be discussed is shown in figure 10. Because points A, B, and C are points of symmetry, only the region bounded by these points need be considered. Furthermore, the distribution of temperature is also symmetric about point O with respect to AO and OC. An enlarged view of the section under consideration is represented in figure 11.

The section has been subdivided into a number of net points $a, b, c, \dots, h$, each separated by a distance Δ^* from adjacent points. The first step in the analysis is the assumption of temperatures at all net points, which can be done by setting up a balance between the total heat produced within the walls and the total outflow of heat from the walls. In terms of the dimensionless variables, this heat balance becomes

$$\frac{1}{C^*} \frac{Nu}{h^* s^*} \int_0^{C^*} \theta^* (h^* + h'^*) dx^* = 1 \quad (30)$$

If, for the initial assumption, $h^* = h'^* = 1$ and θ^* is constant, the following expression is obtained:

$$\theta^* = \frac{s^* k^*}{2Nu} \quad (31)$$

The value of θ^* given by equation (31) is assumed to exist at all net points. The appropriate difference equation at points b, c, d, f , and g is (from equation (18))

$$\theta_1^* + \theta_2^* - \theta_0^* \left[2 + \frac{Nu}{s^* k^*} (h^* + h'^*)_0 \Delta^{*2} \right] + \Delta^{*2} = N_0 \quad (32)$$

where the subscript 0 refers to the point at which the equation is to be applied and subscripts 1 and 2 refer to adjacent points. At point a , which is influenced by three points, the following equation is required:

$$2\theta_b^* + \theta_f^* - \theta_a^* \left[3 + \frac{Nu}{s^* k^*} (h^* + h'^*)_a \Delta^{*2} \right] + \Delta^{*2} = N_a \quad (33)$$

At point e , which is a point of symmetry, the following expression applies:

$$2\theta_a^* - \theta_e^* \left[2 + \frac{Nu}{s^* k^*} (h^* + h'^*)_e \Delta^{*2} \right] + \Delta^{*2} = N_e \quad (34)$$

A similar expression applies at point h . With these equations, the residuals N are calculated at each net point. The point at which N has the largest absolute value is then selected and θ^* at that point is adjusted so that the residual vanishes. The effect of this adjustment on the residuals at adjacent points is calculated with the aid of the appropriate finite-difference equation.

The process is repeated for the point at which the next largest value of the residual appears. Eventually, if the process is repeated often enough, the residuals at all net points approach zero. The final adjusted values of θ^* then satisfy the appropriate equations at all net points.

These values of θ^* should also satisfy the heat balance as given by equation (30). This equation can therefore be used to check the validity of the final temperature distribution. If the check is unsatisfactory, it is necessary to continue the solution of the finite-difference equations by using a smaller net spacing.

The same heat-exchanger configuration is now investigated without making the assumption that the wall thickness is small. The two-dimensional equations are therefore applied. An enlarged view of the shaded portion of figure 9 is shown in figure 12. The lines $\overline{CD}$, $\overline{FG}$, and $\overline{GA}$ are lines of symmetry, and there is no flow of heat across these lines. The temperature distribution along line $\overline{DEF}$ will be symmetric about point E , but there will be a flow of heat across this line. A large number of net points are selected to cover the entire section of the configuration shown in figure 12. (Only

a few of these points are presented in the fig.) An initial value for the temperature along lines $\overline{AB}$ and $\overline{BC}$ is obtained by setting up a balance between the total heat produced within the section and the flow of heat to the gas. In terms of the dimensionless variables, this heat balance becomes

$$\frac{1}{C^*} \int_0^{C^*} h^* \theta^* dx^* = \frac{A^*}{4} \frac{k^*}{Nu} \quad (35)$$

If, for the initial assumption, $h^*=1$ and θ^* is constant, then the following expression for θ^* is obtained:

$$\theta^* = \frac{A^*}{4} \frac{k^*}{Nu} \quad (36)$$

It can now be assumed that the temperature as given by equation (36) exists along the surface of the wall and that a somewhat higher temperature exists at internal points. The assumed temperatures are then adjusted by means of the relaxation method.

The appropriate finite-difference equation for internal points, such as point e , is written as follows:

$$\theta_b^* + \theta_f^* + \theta_n^* + \theta_a^* - 4\theta_e^* + \Delta^{*2} = N_e \quad (37)$$

For points along the boundary, such as point b , the equation is

$$\theta_a^* + \theta_e^* + \theta_c^* - \theta_b^* \left(3 + \frac{Nu}{k^*} h_b^* \Delta^* \right) + \Delta^{*2} = N_b \quad (38)$$

and for points on a line of symmetry, such as point f ,

$$\theta_c^* + 2\theta_e^* + \theta_i^* - 4\theta_f^* + \Delta^{*2} = N_f \quad (39)$$

The appropriate equation for points along $\overline{DEF}$ can be determined by taking advantage of the antisymmetry about this line. At point k , for instance, the equation becomes

$$\theta_n^* + \theta_i^* + \theta_m^* + \theta_j^* - 4\theta_k^* + \Delta^{*2} = N_k \quad (40)$$

Expressions of the type (37) to (40) apply at all net points. The method of determining the actual temperature distribution is the same as the method outlined in the previous section.

The final temperatures along the surface of the wall can be checked with the aid of equation (35). If the check is unsatisfactory, a finer net spacing is required.

RESULTS

One-dimensional solution.—The one-dimensional solution was applied to heat exchangers composed of rectangular and triangular passages, respectively. In each case the passages were staggered in order to minimize the expected hot spots.

The rectangular configuration is represented by figure 10. The height-to-width ratio of each passage in this configuration is 1 to 5. Figure 1 represents the triangular configuration. Each passage in this configuration is an isosceles right triangle.

FIGURE 12.—Relaxation net for rectangular thick-walled heat exchanger.

FIGURE 13.—Temperature distribution for passage of thin-walled triangular heat exchanger (fig. 1).

It has previously been stated that, for each configuration, the temperature distribution in the passage walls is a function only of the parameter Nu/s^*k^* . Accordingly, temperature distributions were calculated for several values of this parameter, ranging from 0.1 to 100. This range of values is believed to include all values actually encountered.

Temperature distributions were calculated according to the method outlined in the previous section of this report and were then checked by equation (30). Local rates of heat transfer $q^* \equiv h^*\theta^*$ were calculated for this purpose. According to equation (30), the mean value of q^* when multiplied by $2Nu/k^*s^*$ should equal 1. Because the finite-difference method of solution is essentially an approximate method, the results were not expected to be exact. All results presented in this section of the report, however, were held to an error of less than 6 percent. The final temperatures were multiplied by a constant scale factor in order to satisfy equation (30) exactly.

Temperature distributions and local rates of heat transfer are presented for the triangular heat exchanger in figures 13 and 14 and for the rectangular heat exchanger in figures 15

and 16. In the temperature plots (figs. 13 and 15), the temperature difference $(t - T_B)$ is referred to the temperature difference $(t - T_B)_c$ for a thin-walled circular tube with the same hydraulic diameter and an internally heated wall with the same physical properties. The temperature difference for the circular tube is given in the nondimensional form by equation (31). Similarly, the ordinate in figures 14 and 16 refers the rate of heat transfer q to the rate of heat transfer from the wall of a thin circular tube q_c . It is believed that

FIGURE 14.—Local rate of heat transfer from passage of thin-walled heat exchanger (fig. 1).

FIGURE 15.—Temperature distribution for passage of thin-walled rectangular heat exchanger (fig. 10).

the interpretation of the temperature and heat-transfer curves is simplified by this final change of ordinates. Temperature distributions for the triangular configuration are shown in figure 13. These curves are presented for values of $Nu/s*k^*$ of 0.1, 1.0, 10, and 100. As was expected, the temperatures peak near the corners of the passage. The largest temperature differences are encountered for large values of the parameter $Nu/s*k^*$. A large value of this parameter indicates a low conductivity of the wall material or a small wall thickness. Both of these conditions are conducive to low rates of heat exchange within the wall. Local rates of heat transfer corresponding to the temperature distributions just discussed are presented in figure 14.

Temperature and heat-transfer curves for the rectangular configuration are shown in figures 15 and 16. The results for this configuration are similar to those for the triangular configuration.

In order to determine when the one-dimensional solution can be used, it is necessary to obtain some information on the temperature difference that exists across the passage walls on normals to the surfaces and to compare this temperature difference with the temperature differences along the surfaces. An estimate of the temperature difference δt_n across the wall may be obtained by calculating this value for a flat plate. The result of this calculation is

$$\delta t_n = \frac{r}{8k} s^2 \quad (41)$$

The equation can be changed to the dimensionless values to yield

$$\delta t_n^* = \frac{s^{*2}}{8} \quad (42)$$

This temperature difference can again be referred to the temperature difference $(t - T_B)_c$ as follows:

$$\frac{\delta t_n}{(t - T_B)_c} = \frac{s^* Nu}{4k^*} \quad (43)$$

The one-dimensional solution applies as long as this value is small as compared with the temperature differences presented in figures 13 and 15.

Two-dimensional solution.—The two-dimensional solution for the temperature field within the heat exchanger depends on two parameters; namely, the dimensionless wall thickness s^* and the value $Nu h^*/k^*$. In addition, the time required to obtain the solution for a special case is much longer than for the one-dimensional solution. Only one example was therefore calculated; namely, the temperature distribution within the walls of a heat exchanger composed of rectangular passages, as shown in figure 9. The ratio of the two side lengths of the rectangle is 1 to 5. The ratio of the hydraulic diameter to the short side of this passage is 1.67 and the dimensionless wall thickness is 0.6. Figure 17 presents the results of the calculation using the relaxation method with a network of 88 points. Lines of constant temperature (isotherms) are shown within the portion of the heat-exchanger walls that is shaded in figure 9. As may be seen, the heat flow within this wall is mainly in the direction normal to the wall surfaces. The maximum temperature differences on any normal to the surface are not very different from the value in a flat plate as calculated in equation (42). The temperature differences along the surface of the wall are

FIGURE 16.—Local rate of heat transfer from passage of thin-walled rectangular heat exchanger (fig. 10).

FIGURE 17.—Isotherms in internally heated walls of thick-walled rectangular heat exchanger. (Shaded portion of fig. 9 shown.) Nu/s^*k^* , 10.0; ratio of flow area to total area, 0.416; s^* , 0.6; y^*/x^* , 1/5.

appreciably smaller than the temperature differences across the wall. The values of the one-dimensional solution cannot therefore be expected to apply to this case. Actually, the temperature difference found in figure 17 along the surface of the wall is considerably greater than for the corresponding one-dimensional case. In addition, heat is generated within the corner area of the rectangular-wall configuration and has to be conducted away along comparatively long paths. An additional temperature increase can therefore be found within this corner area.

CONCLUSIONS

A method to calculate the temperature distribution in a heat exchanger composed of noncircular flow passages with internally heated walls has been presented.

Local heat-transfer coefficients along the circumference of the heat-exchanger passages were obtained from flow measurements made by Nikuradse, assuming similarity between the velocity and temperature fields. The heat-transfer coefficients, as determined in this manner, decrease sharply near the corners of the passages and vanish at the corners. This decrease becomes more pronounced as the corner angle

is increased. Near the corners these coefficients are essentially influenced only by the magnitude of the included angle of the corner.

It was shown that the dimensionless temperature distribution within the passage walls depends on a single parameter, provided the dimensionless wall thickness is small. Numerical evaluations for triangular- and rectangular-passage configurations for a wide range of the aforementioned parameter were carried out. The results of these evaluations are presented so that temperature differences arising in the walls of heat exchangers with the investigated passage shapes for any condition within the range of practical interest can be read off one of several curves. These curves show a temperature increase near the corners of the passages. This increase becomes more pronounced for high Nusselt numbers based on the average heat-transfer coefficient, for low wall-thickness ratios, and for low ratios of the conductivity of the wall to the conductivity of the coolant.

The dimensionless temperature distribution for thick-walled heat exchangers depends on the wall-thickness ratio in addition to the property parameter. Because the time required to calculate temperature distributions in the whole field of interest determined by the two parameters is prohibitive, only a specific example was evaluated numerically. The method of calculation is presented in great detail, however, so that evaluations for other interesting cases can be carried out.

APPENDIX

SOLUTION BY RUNGE-KUTTA METHOD

Equation (16) is of the following form:

$$\frac{d^2 \theta^*}{dx^{*2}} - f(x^*) \theta^* + 1 = 0 \quad (A1)$$

The boundary conditions are

$$\left. \begin{aligned} \left(\frac{d\theta^*}{dx^*} \right)_{x^*=a} &= 0 \\ \left(\frac{d\theta^*}{dx^*} \right)_{x^*=b} &= 0 \end{aligned} \right\} \quad (A2)$$

where a and b are points of symmetry.

In general, a solution of equation (A1) could be obtained by assuming an initial value of θ^* at point a in addition to the first of the boundary conditions (A2) and by working the solution toward point b using a numerical method of integration. If the boundary condition at point b is not satisfied,

the solution has to be repeated with a new initial value. This trial-and-error process is tedious and can be avoided by splitting equation (A1) in such a manner as to keep an undetermined constant c in the solution. This constant is finally determined by satisfying the second boundary condition. Let

$$\theta^* = \theta_1^* + c\theta_2^* \quad (A3)$$

$$\frac{d^2 \theta_1^*}{dx^{*2}} - f(x^*) \theta_1^* + 1 = 0$$

$$\frac{d^2 \theta_2^*}{dx^{*2}} - f(x^*) \theta_2^* = 0$$

where

$$\begin{aligned} \theta_1^*(a) &= 0 & \theta_2^*(a) &= 1 \\ \left(\frac{d\theta_1^*}{dx^*} \right)_a &= 0 & \left(\frac{d\theta_2^*}{dx^*} \right)_a &= 0 \end{aligned}$$

These expressions still satisfy equation (A1) and the first of the boundary conditions (A2). After the solutions for θ_1^* and θ_2^* have been numerically obtained, the constant c is determined so that the boundary condition at point b is fulfilled; thus

$$\left(\frac{d\theta_1^*}{dx^*}\right)_b + c\left(\frac{d\theta_2^*}{dx^*}\right)_b = 0$$

or

$$c = -\frac{\left(\frac{d\theta_1^*}{dx^*}\right)_b}{\left(\frac{d\theta_2^*}{dx^*}\right)_b}$$

The final temperature distribution is given by equation (A3).

The temperature distribution in a thin-walled heat exchanger with triangular passages was calculated in this manner (for $Nu/s^*k^*=10$) and was compared with the corresponding curve in figure 13. The Runge-Kutta method (reference 10) was used for the numerical integration. This particular comparison showed differences of 2.2 percent of the temperature ratio near the corners of the passages and smaller deviations elsewhere. The temperature curves are uncertain to the same order of magnitude, however, because

of the freedom in the extrapolation of the heat-transfer-coefficient curves. The simpler relaxation method is therefore regarded satisfactory for the present purpose.

REPORT 1023

DIFFUSION OF CHROMIUM IN ALPHA COBALT-CHROMIUM SOLID SOLUTIONS¹

By JOHN W. WEETON

SUMMARY

Diffusion of chromium in α cobalt-chromium solid solutions was investigated in the range 0 to 40 atomic percent at temperatures of 1360°, 1300°, 1150°, and 1000° C. The diffusion coefficients were found to be relatively constant within the composition range covered by each specimen.

The activation heat of diffusion was determined to be 63,600 calories per mole. This value agrees closely with the value of 63,400 calories per mole calculated by means of the Dushman-Langmuir equation. The exponential equation relating diffusion coefficient D to temperature T is as follows:

$$D = 0.443e^{-\frac{63,600}{RT}}$$

where R is the gas constant.

When compared with the diffusion data previously obtained by other investigators for most alloy systems, the diffusion rates of chromium in α cobalt-chromium were found to be low; considerably higher temperatures were required to produce diffusion coefficients of the same order of magnitude as were previously found for most substitutional alloys. This behavior is congruous with the fact that cobalt-chromium based alloys such as Haynes Stellite 21 have good high-temperature characteristics.

Chromium diffusivity from α cobalt-chromium alloys into pure cobalt is greater than chromium diffusivity from high-chromium α -alloys to low-chromium α -alloys for all concentration gradients studied.

INTRODUCTION

Several important high-temperature alloys (Haynes Stellite 21, X-40, 61, and 422-19) consist primarily of cobalt and chromium; Haynes Stellite 21 has been one of the most extensively used turbojet-blade alloys in the United States. Because of the importance of cobalt-chromium based alloys and because diffusion controls many reactions within solid metals, an investigation was conducted at the NACA Lewis laboratory to determine the diffusion coefficients of chromium into α cobalt-chromium solid solutions, to determine the dependence of these coefficients on concentration, and to evaluate the basic constants Q and A in the exponential equation relating temperature and diffusion (reference 1)

$$D = Ae^{-\frac{Q}{RT}}$$

where

A constant, (cm²/sec)

D diffusion coefficient, (cm²/sec)

Q activation heat of diffusion, (cal/mole)

R gas constant, (cal/(mole) (°K))

T temperature, (°K)

The method employed consisted in pressure-welding cobalt and cobalt-chromium bars unlike in composition, annealing

these joined bars at constant temperatures to cause an inter-diffusion of atoms, and determining the distribution of chromium through the diffusion zones thus formed by machining and chemically analyzing several successive turnings through this zone.

Diffusion coefficients were determined for 11 specimens at the nominal temperatures and composition ranges shown in the following table:

CHROMIUM CONTENT OF WELDED SPECIMENS
(ATOMIC PERCENT)

1360° C			1300° C			1150° C			1000° C		
Specimen	Composition		Specimen	Composition		Specimen	Composition		Specimen	Composition	
	Low-Cr half	High-Cr half		Low-Cr half	High-Cr half		Low-Cr half	High-Cr half		Low-Cr half	High-Cr half
1	0	22.20	3	0	28.00	6	13.15	38.65	8	0	24.92
2	9.60	28.06	4	9.60	41.15	7	0	28.06	9	9.80	39.97
11	0	28.00	5	9.98	39.20						
			10	0	28.15						

With the exception of specimens 1 and 2, which were originally intended for annealing at 900° C, the specimens were made to cover most of the range of the α field in the cobalt-chromium equilibrium diagram (fig. 1).

FIGURE 1.—Cobalt-chromium equilibrium diagram from reference 2. Also drawn are composition ranges at annealing temperatures used in this investigation.

¹ Supersedes NACA TN 2218, "Diffusion of Chromium in α Cobalt-Chromium Solid Solutions" by John W. Weeton, 1950.

Diffusion coefficients were calculated by the Grube method (reference 3), although the Matano method (reference 3) was also used in two cases.

APPARATUS AND PROCEDURE

Materials.—Cobalt rondels and electrolytic chromium of high purity were used as raw materials. Spectrographic and wet chemical analyses were made of the rondels. Colorimetric analyses, made for elements that were shown to be present by the spectrograph but were not detectable by wet chemical methods, are less than 0.01 percent. The results of the analysis of cobalt rondels and of an analysis of electrolytic chromium made by the supplier, the Bureau of Mines, are given in the following table:

IMPURITIES IN COBALT AND CHROMIUM

Cobalt rondels (percent)		Electrolytic chromium (percent)	
Ni	0.38	Fe	0.31
Fe	.10	O	.17
Cu	.08		
Mn	.01		
Sn	.01		
Ag	.01		
Pb	.01		
Ti	.01		
V	.01		
C	*, 14, .20		

* Determined by commercial laboratory.

It will be shown that the carbon content was considerably reduced during melting.

Melting and casting.—Cobalt and cobalt-chromium melts of nominally 0, 10, 25, and 35 percent-by-weight chromium (0, 11, 27, and 38 atomic percent) were made in zirconium silicate crucibles, using a 100-kilowatt, 9600-cycle-per-second induction unit. The rondels were first melted with no protective atmosphere and were held at temperatures of 1593° to 1649° C (2900° to 3000° F) for 5 to 10 minutes to burn out the carbon. As a result of this procedure, the carbon was reduced to less than 0.06 percent in most cases, but the oxide content of the metal was probably increased.

Where chromium additions were required, an atmosphere of argon was kept over the surface of the melt from the time the addition was made until the pouring time, a total period of 10 to 20 minutes. Chromium was not charged with the cobalt because chromium prevents oxidation and removal of almost all the carbon.

Castings were made in copper molds and, except for the heads, were shaped like truncated cones 4 inches long, 1¼ inches in diameter at the top, and ⅞ inch in diameter at the bottom. Chemical analyses made from both ends of the castings containing chromium indicated that the churning action of the induction current produced an excellent degree of chemical homogeneity; differences in chromium analyses made from the large and the small ends of castings ranged from 0.02 to 0.15 percent.

Heat treatment prior to forging.—As a precautionary measure, the samples containing chromium were soaked at 1176° to 1231° C (2150° to 2250° F) for ½ hour and then oil-quenched. This treatment was intended to reduce the

possibility of cracking the samples if insufficient soaking time were allowed prior to forging.

Forging.—The tapered castings, which were forged at a commercial laboratory, were upset one or two times and were fullered out to an approximately uniform diameter of 1 inch. The reduction in length occurring when the castings were upset varied from approximately 20 to 50 percent. Forging at temperatures from 982° to 1093° C (1800° to 1900° F) reduced the grain size from grains as large as ¼ inch to smaller, more uniformly shaped grains that varied from A. S. T. M. grain size 5 to small macroscopic grains approximately ⅛ inch.

Homogenizing heat-treatment.—The samples containing chromium were annealed at 1204° C (2200° F) for 3 hours in a helium atmosphere for further homogenization. Results presented herein indicate that this treatment does little more than stress-relieve the specimens.

Machining of bars to be welded.—Cylinders ⅞ inch in diameter and 1¼ to 2¼ inches in length were machined from the forged bars. Both ends of these cylinders were surface ground to produce flatness and one end of each bar was then lapped by a gage-block manufacturer until it could be "wrung" to another bar.

Welding of dissimilar bars or cylinders.—Lapped specimens of unlike compositions were placed in the holders shown in figure 2. The upper holder was bolted to a 120,000-pound tensile machine and the lower one was placed on the table of the machine. A load of 5000 pounds was applied after the cylinders were centered in an induction coil and the holders were alined. The specimens were heated with a portable, 35-kilowatt, 360,000-cycle-per-second, spark-gap induction unit.

FIGURE 2.—Pressure-welding apparatus.

During the heat-up time, which varied from $\frac{1}{2}$ to $1\frac{1}{2}$ minutes, the tendency for the load to increase as thermal expansion of the cylinders took place was reduced by the tensile-machine operator, who kept the pressure reasonably constant (within ± 200 pounds). Because a skin effect could be produced by raising the specimen temperature too rapidly, the power to the induction machine was turned on and off to allow an even heat distribution across the weld surface. When the temperature, which was read with an optical pyrometer, reached a point between 982° and 1038° C (1800° to 1900° F), the load was reduced to 4000 pounds to prevent excessive bulging. This load was maintained during the welding period of $1\frac{1}{2}$ to $2\frac{1}{2}$ minutes at 1121° to 1204° C (2050° to 2200° F). Bulging was kept at a minimum to prevent curving of the interface. Uneven heating or misalignment of specimens caused bent or distorted welds. Satisfactory welds were strong enough to be hammered and bent.

First welding attempts were unsuccessful because the surfaces were not lapped to a gage-block finish and, as a result, considerable oxides were formed in the welds. An attempt was also made to surround the apparatus shown in figure 2 with a vacuum-tight shell into which argon or helium could be bled during welding. However, in spite of insulating the container and the coil from the work, extensive arcing in these atmospheres prevented welding. This method was then abandoned in favor of the one used.

Metallographic examination after welding.—Flat planes were ground lengthwise on the welded specimens for metallographic examination (fig. 3). In the etched and unetched

FIGURE 3.—Pressure-welded specimens with flat planes polished for metallographic examination.

conditions, the weld interfaces were examined for oxides, weld curvature, and other imperfections. Examples of satisfactory and unsatisfactory welds are shown in figure 4. Diffusion zones formed during welding were measured with a micrometer eyepiece and a research metallograph. The thickness of these zones, ranging from less than 0.0001 to 0.00046 inch (<0.00254 to 0.0117 mm), were considered negligible (fig. 4 (b)).

Machining prior to anneal.—Specimens $1\frac{1}{4}$ inches long and $\frac{1}{16}$ to $\frac{1}{8}$ inch in diameter, which included the weld interface, were turned from the welded specimens. Care was exercised during machining to make certain that the axes of these cylinders were perpendicular to the weld interfaces.

Calibration of instruments.—The thermocouple wires used during the diffusion anneal, subsequently to be described, were taken from a coil calibrated by the National Bureau of Standards. The potentiometer used to read the temperature was calibrated at the Lewis laboratory.

Diffusion anneal.—

1. **Furnaces:** Most of the specimens were annealed in a furnace using silicon carbide heating elements controlled by a self-balancing, self-standardizing, indicating pyrometer. The furnace, an eight-element unit, and the controller were wired so that four elements cycled on and off while the other four received power at all times. A zirconium silicate tube was placed in the furnace as shown in figure 5. The specimens to be annealed were placed in a porous-brick holder along with a platinum-platinum-rhodium thermocouple. A period of 1 to 3 hours was required to stabilize the furnace temperature after loading. Fluctuations of more than $\pm 4^\circ$ C ($\pm 7.2^\circ$ F) were rare and were of short duration. Time-temperature plots were made for all of the specimens except those annealed at 1000° C for 87.7 days. A typical time-temperature plot for specimen 4 is shown in figure 6. The plots were integrated with a planimeter to find a weighted average temperature, which was then corrected for the thermocouple wire calibration and converted to $^\circ$ C (table I).

Specimens 8 and 9, which were annealed at 1000° C, were first annealed for a month in the silicon-carbide-element furnace and then transferred to a platinum-wound-resistance furnace. This furnace and a commercial light-beam-galvanometer-type photoelectric-cell controller were located in a room kept at constant temperature. Except for a temporary breakdown, the furnace was controlled within $\pm 4^\circ$ C ($\pm 7.2^\circ$ F).

2. **Atmospheres:** During loading of the furnace, a large quantity of argon was blown through the tube to prevent oxidation of the specimen. The gas flow was decreased after the stopper was sealed in the loading end of the zirconium silicate tube. The argon flow was completely shut off, the rubber tube to the bubble jar was clamped shut, and the zirconium silicate tube and the argon line, including the drying towers, were evacuated by a pump capable of evacuating the system to a pressure of 1 millimeter of mercury when no leaks were present. This evacuation seated the rubber stopper and made it possible to locate any leaks in the thermocouple and the stopper seals. Argon was then bled into the evacuated zirconium silicate tube, which was then re-evacuated. This procedure was repeated five times to flush the tube. The vacuum pump was then closed and argon was allowed to pass through the system and out of the bubble jar.

Specimens 3 and 4 were placed in the furnace without the aid of the vacuum pump but upon removal after annealing were appreciably scaled (table I). After the system was evacuated, the drying towers (commercial metallic towers) were found to be leaking. Laboratory-type glass drying

- (b) Satisfactory weld interface. Etchant, 10-percent nitric acid in ethyl alcohol; magnification, $\times 750$. Examination of heavily etched surface reveals approximately half of diffusion zone (distance between dark area and weld interface, approximately 0.00012 in. (0.0028 mm) wide) caused by welding. Etchant has attacked only cobalt half of weld.

FIGURE 4.—Appearance of satisfactory and unsatisfactory welds. (Magnification increased 10.4 percent in printing.)

towers were then installed and scaling was somewhat reduced. As an added precaution in annealing specimens 1, 2, 5, and 8 to 11, a mixture of hydrogen and helium, rather than argon, was passed through the zirconium silicate tube for a few hours after the system was sealed in order to scavenge oxygen from the bricks inside the tube. Argon was used after the hydrogen-helium purge and scaling was decreased to a negligible amount, especially when it is considered that loading and unloading the furnace could account for almost all the scale indicated for these specimens (table I).

Examination and reduction of diameter after anneal.—

After the anneal, flat surfaces for metallographic examination were again ground on the specimens so that an estimate of the reduction in diameter needed to eliminate surface effects could be made. In most cases, $\frac{1}{32}$ to $\frac{3}{32}$ inch of metal was removed. Flat surfaces were again ground and examined (fig. 7), and where surface scaling was appreciable a thin turning was chemically analyzed for comparison with the original analyses. Oxide accumulations in the interface zone were also observed (fig. 8). The specimens were heavily etched and approximate measurements of total diffusion

FIGURE 5.—Sectional view of annealing furnace showing specimen holder and thermocouple placement.

zones were made with a micrometer eyepiece. This measurement was made to determine the number of machining cuts required to cover the diffusion zone.

Machining successive layers through diffusion zone.—Before machining successive layers through the diffusion zone, excess metal was removed from the low-chromium half of the specimen to establish a reference surface from which cuts for analyses were made. From 0.1 to 0.125 inch (2.54 to 3.175 mm) of metal was left between the weld interface (determined metallographically) and the reference surface. Tungsten carbide cutting tools were used for all machining operations.

A series of turnings was made across the entire cross section starting at the reference surface perpendicular to the axis of the cylinder. After each turning, the distance machined was measured and the chips were gathered for chemical analysis. The cuts farthest from the interface were 0.010 inch thick (0.254 mm); cuts were reduced to a thickness from 0.003 to 0.005 inch (0.0762 to 0.127 mm) in the diffusion zone. In all the specimens except specimen 3, the entire zone was covered by the smallest cuts made.

Three methods of machining successive cuts through the diffusion zone were used. In the first method, used for specimens 2 to 7, the cylinders with machined reference surfaces were chucked in a large rigid lathe. The head of this lathe contained a large cast-iron face plate that was machined for use as a surface plate. All cuts less than 0.007 inch thick were measured from the surface plate with a surface dial gage that could be read to 0.0001 inch and estimated to 0.00001 inch. Thus, removing the work from the chuck after each cut was unnecessary. A calibration of the dial showed that cuts of 0.003 inch needed no corrections and that cuts of 0.005 inch were in error by as little as 0.00006 inch, or approximately 1 percent. If human errors are taken into consideration, the maximum machining errors were believed to be no more than 2 percent. These

FIGURE 6.—Typical time-temperature plot for diffusion-anneal period in annealing furnace (specimen 4). Temperatures have not been corrected with platinum-platinum-rhodium wire calibration.

dial corrections were considered negligible and have been omitted in the calculations.

The second method, similar to the preceding one, was used for specimens 1, 8, and 9. The chips were machine off with a high-precision vertical jig borer (SIP Hydrostatic-7), which was kept in an air-conditioned room, and a calibrated surface gage was used to measure the cuts. Machining errors were measured with a micrometer and were determined by comparing the total amount of metal removed after making all the necessary cuts with the sum of all the small cuts measured with the surface dial gage. In specimen 8, with a total of 48 cuts, the error was 0.25 percent, whereas in specimen 9, the error was 2 percent in the same number of cuts.

The third method, used for specimens 10 and 11, was the most accurate as well as the most complicated. The vertical jig borer was again used, but the thickness of each cut was measured by an electronic height gage that measured the differences in height between stacks of gage blocks and the specimen surface to 0.00001 inch. As a further assurance that no discrepancies would occur, a height gage (surface

FIGURE 7.—Specimen after diffusion anneal.

plate checker) was also used in conjunction with the electronic gage. With this gage, it was possible to measure the over-all height of the specimen to 0.00001 inch after each layer was machined off. Differences in over-all height were compared with the thickness of each cut as measured with the electronic height gage and the stacks of gage blocks. In the two specimens so machined, the error was 0 percent in 36 cuts for specimen 11 and 0.025 percent in 32 cuts for specimen 10.

Chemical analyses.—At least two and usually three analyses by a persulfate-oxidation method were made at the Lewis laboratory for every sample machined from the diffusion zone.

Methods of calculating diffusion coefficients.—The diffusion coefficients for all specimens were calculated by the Grube method (reference 3). In addition, calculations using the Matano method (reference 3) were made for specimens 3 and 5. The Matano method was not used throughout because it was extremely time consuming and the results closely paralleled those calculated by the Grube method.

The metric system was used in plotting concentration-penetration curves and diffusion coefficients were calculated in this system to conform with previous work. The data points were plotted at distances halfway between successive cuts, which were measured from a reference plane. Leveling-off points of the curves were drawn from mathematical averages of several data points, some of which are not shown in the figures.

Diffusion coefficients were calculated from the concentration-penetration curves using the following equation (Grube method):

$$\frac{C-C_0}{C_1-C_0} = \frac{1}{2} \left(1 \pm \frac{2}{\sqrt{\pi}} \int_0^{\omega} e^{-\omega^2} d\omega \right)$$

where

C	chromium concentration, atomic percent
C_0	chromium concentration of low-chromium bar, atomic percent
C_1	chromium concentration of high-chromium bar, atomic percent
ω	$= \frac{x}{2\sqrt{Dt}}$
D	diffusion coefficient, (cm ² /sec)
x	distance from Grube interface, (cm)
t	time, (sec)

Positive values were used for calculations made from the high-chromium portions of the concentration-penetration curves to the right of the Grube interface, whereas negative values were used for calculations made from the low-chromium portions of the curves to the left of the Grube interface.

The Grube interface is the distance in the diffusion zone at which the concentration is halfway between the lower and upper concentrations C_0 and C_1 , respectively (figs. 9 (d) and 9 (f)).

Let

$$H\left(\frac{x}{2\sqrt{Dt}}\right) = \pm \frac{2}{\sqrt{\pi}} \int_0^{\omega} e^{-\omega^2} d\omega$$

$$\omega = \frac{x}{2\sqrt{Dt}}$$

FIGURE 8.—Central portion of diffusion zone of specimen 10. Annealed 7.17 days at 1297° C; etchant, 5-percent nitric acid in ethyl alcohol followed by aqua regia in glycerine; magnification, $\times 100$. Photograph shows accumulation of oxides near center of diffusion zone. (Magnification increased 6.2 percent in printing.)

Then

$$\frac{C-C_0}{C_1-C_0} = \frac{1}{2} \left[1 \pm H(\omega) \right]$$

$$H(\omega) = \pm 2 \left(\frac{C-C_0}{C_1-C_0} - 0.5 \right)$$

The value of ω may be obtained from probability tables and inasmuch as

$$\omega = \frac{x}{2\sqrt{Dt}}$$

then

$$D = \frac{x^2}{\omega^2} \frac{1}{4t}$$

The final equation indicates that D is very sensitive to x , the machined distance.

RESULTS

Concentration-penetration curves of all specimens are plotted in figure 9. Several of these curves, such as those for specimens 3, 4, 7, 8, and 10 (figs. 9 (d), 9 (e), 9 (i), 9 (j), and 9 (g), respectively) are very symmetrical. When data from these curves are plotted on a probability graph in the form

FIGURE 9.—Concluded. Concentration-penetration curves.

$(C-C_0)/(C_1-C_0)$ against the distance from the Grube interface, approximately straight lines are obtained (fig. 10). In these cases, the diffusion coefficient D is almost invariant with the concentration C . The curves pass through the point $(x=0, \frac{C-C_0}{C_1-C_0} \times 100 = 50)$.

Other curves, such as that for specimen 5 (fig. 9 (f)), bend slightly from a smooth curve in the upper right, or high-chromium portions, of the diffusion curves. These bends also show up in the probability plots (fig. 10 (f)). Deviations from

smooth concentration-penetration curves and from straight lines in the probability plots could be a function of concentration. The deviations, however, are believed to be caused by oxide segregations that may have been present in the high-chromium half of the welded specimens before the diffusion anneal or that may have formed during the annealing by migrations of oxides that were originally randomly scattered throughout the matrix of the metal. The metallographic examinations and the smooth lower portions of most of the curves indicate that migration is the most probable case.

FIGURE 10.—Continued. Plots of $(C-C_0)/(C_1-C_0)$ against distance from Grube interface.

Diffusion coefficients calculated by the Grube method from the concentration-penetration curves are plotted against concentration in figure 11. Values of diffusion coefficients obtained from the extreme ends of the diffusion-penetration curves and from portions near the Grube interfaces were omitted from the plot because they are inherently inaccurate. The degree of reproducibility of data appears good, as shown in the cases of specimens 3 and 10, and 4 and 5, which were annealed at $1300^\circ \pm 3^\circ$ C.

Specimens 1 and 2, prior to annealing at 1360° C, were annealed at 900° C for several weeks. Meanwhile, diffusion

coefficients were obtained at 1300° and 1150° C and rough calculations from these preliminary data showed that an annealing time of about 8 years at 900° C would be required to produce a diffusion zone comparable in thickness to the smallest zone obtained at the higher temperatures. Inasmuch as the annealing time at 900° C was insignificantly small, the specimens were reannealed at 1360° C to obtain additional data. Because the specimens were originally intended for heat treatment at 900° C, the composition range covered by specimens 1 and 2 is small compared with what would be possible at 1360° C.

 FIGURE 10.—Continued. Plots of $(C-C_0)/(C_1-C_0)$ against distance from Grube interface.

 FIGURE 10.—Concluded. Plots of $(C-C_0)/(C_1-C_0)$ against distance from Grube interface.

FIGURE 11.—Diffusion coefficients against concentration. (Data to left of 8 atomic percent not plotted for specimen 1 because of quench crack that formed after diffusion took place.)

The upper half of the curve of specimen 1 (fig. 9 (a)) is satisfactory and calculations were made from it by the Grube method. The lower portion, however, was inaccurate as a result of a quench crack formed by cooling the specimen in an air blast as it was removed from the annealing furnace.

The composition of specimen 9 extends into the $\alpha + \gamma$ field (fig. 1), but because it is close to the α -phase boundary, only a small percentage of γ would be present. Since the γ -phase was not observed during the metallographic examinations, the calculated diffusion coefficients would therefore be reasonably accurate.

In spite of several metallographic inspections, a strip of oxide $\frac{1}{2}$ inch deep extending halfway about the periphery of specimen 11 was noticed as it was being machined. Approximately 5.4 percent of the area of the interface was blocked. Inasmuch as this area is a small portion of the total area, the data for specimen 11 were not discarded.

A plot of diffusion coefficients against concentration (fig. 12) shows the small differences between values determined by the Grube and the Matano methods.

The relation between diffusion coefficients and reciprocal temperatures are shown in figure 13. The upper and lower curves are plotted from data obtained for 16-atomic-percent chromium because these values are close to averages of the flat portions of the curves of figure 11. The upper curve represents diffusion coefficients obtained from specimens of cobalt welded to cobalt-chromium alloys, whereas the lower curve represents alloys approximately 9- to 14-atomic-percent chromium welded to alloys of approximately 28- to 41-atomic-percent chromium.

FIGURE 12.—Comparison of diffusion coefficients calculated by the Grube and Matano methods.

By use of the dashed curve, which was drawn halfway between the upper and lower solid curves in figure 13, and of the exponential equation (reference 1)

$$D = Ae^{-\frac{Q}{RT}}$$

the activation heat of diffusion Q and the constant A were determined to be

$$Q = 63,600 \text{ (cal/mole)}$$

$$A = 0.443 \text{ (cm}^2\text{/sec)}$$

The value of Q was determined from the slope of the dashed curve because

$$2.303 \frac{(\log D_1 - \log D_2)}{\frac{1}{T_1} - \frac{1}{T_2}} = -\frac{Q}{R}$$

and A was determined from the preceding exponential equation, using the value of Q obtained and values of D and $1/T$ chosen from the dashed curve.

The diffusion behavior of chromium in α cobalt-chromium alloys may be compared with that of other metal systems in figure 14, where values from the dashed curve of figure 13 are replotted for the comparison. The curves for the other alloy systems were taken from the graphs of references 3 to 9.

DISCUSSION OF RESULTS

Diffusion coefficients are relatively constant within the concentration ranges of each specimen. Appreciable differences between diffusion coefficients, however, were obtained from specimens of pure cobalt welded to α cobalt-chromium alloys and specimens of low-chromium α -alloys welded to high-chromium α -alloys at each nominal annealing temperature; the diffusion coefficients for specimens of pure cobalt welded to α cobalt-chromium alloys were larger (figs. 11 and 13).

The differences in diffusion coefficients are not the results of such experimental variables as:

- (1) Differences in sources of materials because single supplies of cobalt and chromium were used in this study
- (2) Differences in annealing temperatures because specimens 1 and 2 and specimens 8 and 9 were annealed together at identical temperatures and the remaining specimens were annealed at temperatures very close to the desired nominal temperatures
- (3) Differences due to the closeness of the high-chromium specimens to the α - γ region because specimens 1 and 2 were well within the α region

A somewhat similar observation may be made from figure 14, where curves 4 and 5 represent the diffusion of pure copper into pure gold, and copper from a gold-copper alloy into gold, respectively.

The experimental data give additional confirmation to the Dushman-Langmuir equation

$$D = \frac{Q}{Nh} \delta^2 e^{-\frac{Q}{RT}}$$

where

D diffusion coefficient, (cm²/sec)

Q activation heat of diffusion, (cal/mole)

N Avogadro's number

h Planck's constant, (cal-sec)

δ distance of closest approach of atoms, $\frac{a_0}{\sqrt{2}}$, (cm)

a_0 lattice parameter

R gas constant, (cal/(mole)(°K))

T temperature, (°K)

The following value of Q has been calculated by arbitrarily selecting a point on the dashed curve of figure 13 to obtain a D value for a given temperature:

$$Q = 63,400 \text{ (cal/mole)}$$

Values used in the calculation are as follows:

$$D = 6 \times 10^{-11} \text{ (cm}^2\text{/sec)}$$

$$\frac{1}{^\circ K} = 7.1 \times 10^{-4}$$

$$a_0 = 3.54 \times 10^{-8} \text{ (cm) (reference 10)}$$

The value of Q compares favorably with the value of $Q = 63,600$ (cal/mole) obtained from the slope of the dashed curve.

The diffusion rates of chromium in α cobalt-chromium were very low compared with those of most alloy systems for which diffusion data had been previously obtained. For

example, it can be determined from figure 14 that a high temperature (1031°C) is required to produce $\log D = -11$ for chromium in cobalt, whereas annealing temperatures of 362° , 628° , and 784°C are required for Mg in Al, Zn in Cu, and Pt in Au, respectively. The sluggishness of diffusion is congruous with the fact that cobalt-chromium base alloys have good high-temperature characteristics.

The activation heat of diffusion for chromium in α cobalt-chromium alloys is greater than that for most systems previously investigated, with tungsten alloys being the chief exceptions (reference 11). Higher activation heats of diffusion show up in the form of steeper slopes on the curve of $\log D$ against $1/^\circ K$ (fig. 14).

FIGURE 13.—Diffusion coefficients against $1/^\circ K$. Diffusion coefficients were plotted from data for 16-atomic-percent chromium.

FIGURE 14.—Comparison of diffusion behavior of chromium in α cobalt-chromium alloys with other substitutional solid-solution alloys.

SUMMARY OF RESULTS

Diffusion of chromium in α cobalt-chromium solid solutions was investigated at temperatures of 1360°, 1300°, 1150°, and 1000° C and the following results obtained:

1. The exponential equation relating diffusion coefficient D and temperature T is as follows:

$$D = 0.443e^{-\frac{63,600}{RT}}$$

where R is the gas constant. The activation heat of diffusion is 63,600 calories per mole.

2. When compared with the diffusion data previously obtained by other investigators for most alloy systems, the diffusion rates of chromium in α cobalt-chromium were found to be low; considerably higher temperatures were required to produce diffusion coefficients of the same order

of magnitude as were previously found for most substitutional alloys.

3. Diffusion coefficients are relatively constant within the concentration ranges covered by each specimen.

4. Chromium diffusivity from α cobalt-chromium alloys into pure cobalt is greater than chromium diffusivity from high-chromium α -alloys to low-chromium α -alloys for all concentration gradients studied.

5. The results of this investigation are further confirmation of the Dushman-Langmuir equation. The value for the activation heat of diffusion calculated from this equation agrees closely with the experimentally determined value (63,400 cal/mole as calculated against 63,600 cal/mole obtained from experimentation).

REPORT 1024

CALCULATION OF THE LATERAL CONTROL OF SWEEP AND UNSWEEP FLEXIBLE WINGS OF ARBITRARY STIFFNESS¹

By FRANKLIN W. DIEDERICH

SUMMARY

A method similar to that of NACA Rep. 1000 is presented for calculating the effectiveness and the reversal speed of lateral-control devices on swept and unswept wings of arbitrary stiffness. Provision is made for using either stiffness curves and root-rotation constants or structural influence coefficients in the analysis. Computing forms and an illustrative example are included to facilitate calculations by means of the method.

The effectiveness of conventional aileron configurations and the margin against aileron reversal are shown to be relatively low for swept wings at all speeds and for all wing plan forms at supersonic speeds.

INTRODUCTION

Adequate lateral control constitutes one of the more significant design requirements for airplanes. The ability of the airplane to enter a roll is determined by the control power and is measured by the maximum available rolling moment resulting from lateral-control deflection. A measure of the degree of lateral maneuverability is the helix angle at the wing tips corresponding to the highest rate of roll; the lateral maneuverability depends both on the control power and the damping in roll.

The control power and the damping in roll are affected by structural flexibility. Control deflection ordinarily gives rise to aerodynamic loads which tend to deform the wing structure in such a way as to reduce the loads on it and thus to reduce the control power. If the dynamic pressure of the air stream is sufficiently high, the amount of lift which results from the structural deformation may be sufficient to nullify the effect of the control deflection. The speed and dynamic pressure corresponding to this condition are known as the aileron reversal speed or reversal dynamic pressure, since at a slightly higher dynamic pressure a control deflection in a given direction would result in a rolling moment in a direction opposite to that of the moment on a similar rigid wing.

The present report is concerned with an analysis of these problems for swept and unswept wings of arbitrary stiffness. The method is based on the analysis of loading of flexible wings presented in reference 1. Since suitable aerodynamic influence coefficients are not yet available for antisymmetric

lift distributions, aerodynamic-induction effects on the lift distribution are taken into account only as an over-all correction and as a slight reduction of the load at the tip, as in reference 1. The method is formulated in such a manner, however, that aerodynamic influence coefficients may easily be included as soon as they become available.

The numerical analysis required in any given practical case constitutes an extension of the calculations outlined in reference 1. The computing forms for the additional calculations required for an analysis of lateral-control effectiveness or reversal are included in the present report. Their use is described in the section entitled "Application of the Method," which may be read without reference to the derivation of the method. The material presented in reference 1 which is pertinent to the present analysis is included herein. As an example illustrating the method, the lateral-control effectiveness and reversal of the wing considered in reference 1 are analyzed in this report. The reversal speeds of several wings derived from this wing by shifting the elastic axis and rotating the wing are calculated to demonstrate some general effects of sweep on the aileron reversal speed.

$c_{m_{c/4}}$	section pitching-moment coefficient referred to quarter-chord point
$C_{L\alpha}$	wing lift-curve slope, per radian

¹ Supersedes NACA RM LSH24a, "Calculation of the Effects of Structural Flexibility on Lateral Control of Wings of Arbitrary Plan Form and Stiffness" by Franklin W. Diederich, 1948.

$C_{L_{\alpha_e}}$	effective lift-curve slope for twist distributions, per radian	S	total wing area including part of wing covered by fuselage, square inches
C_l	rolling-moment coefficient $\left(\frac{\text{Rolling moment}}{qSb}\right)$	s_m	trace of matrix $[A_R]^m$
$[C_3']$	matrix converting torques due to distributed loads to torques due to concentrated torques	t	running torque due to air load about axes perpendicular to the plane of symmetry, inch-pounds per inch
$[C_4']$	matrix converting bending moments due to distributed loads to bending moments due to concentrated loads	w	fuselage width, inches
cp_s	section center of pressure due to aileron deflection measured from leading edge of chord, fraction of chord	w_e	distance between the effective root and the innermost complete section of the torsion box perpendicular to the elastic axis, inches
EI	bending stiffness in planes perpendicular to the elastic axis, pound-inches ²	y	lateral ordinate measured from plane of symmetry, inches
e	location of elastic axis measured from leading edge, fraction of chord	α_s	angle of attack due to structural deformation, radians
e_1	dimensionless distance along chord from reference axis to section aerodynamic center ($e-a$)	α_δ	angle of attack equivalent to unit aileron deflection $\left(\frac{dc_l/d\delta}{dc_l/d\alpha}\right)$
e_2	dimensionless distance along chord from reference axis to section center of pressure due to aileron deflection (cp_s-e)	δ	aileron deflection measured in planes parallel to the direction of flight, radians
g	factor proportional to the rolling-moment coefficient due to aileron deflection defined by equation (16)	ϵ	moment-arm ratio (e_2/e_1)
GJ	torsional stiffness in planes perpendicular to the elastic axis, pound-inches ²	η	lateral distance from wing root, inches
$[I], [I']$	integrating matrices for single integration from tip to root	Λ	angle of sweepback (measured to the reference axis unless specified otherwise), degrees
$[II], [II']$	integrating matrices for double integration from tip to root	$[\Phi_P]$	influence-coefficient matrix for wing twist in planes parallel to the air stream due to concentrated unit loads applied at the reference axis, radians per pound
$[I'_1], [II'_1]$	first rows of matrices $[I']$ and $[II']$, respectively	$[\Phi_T]$	influence-coefficient matrix for wing twist in planes parallel to the air stream due to concentrated unit torques applied in planes parallel to the air stream, radians per inch-pound
$[II'_0]$	integrating matrix defined by equation (14)		
k	dimensionless parameter $\left(\frac{(GJ)_r}{(EI)_r} \frac{b'/2}{e_1 c_r \cos^2 \Lambda} \tan \Lambda\right)$	Subscripts:	
κ	wing lift-curve-slope ratio ($C_{L_{\alpha_e}}/C_{L_{\alpha}}$)	$c/2$	midchord
l	running air load per unit length perpendicular to the plane of symmetry, pounds per inch	D	divergence
M_0	free-stream Mach number	fw	flexible wing
$\frac{pb}{2V}$	wing-tip helix angle	i	inboard end of aileron
$Q_{\alpha_M}, Q_{\alpha_T}$	root-twist constants	o	outboard end of aileron
q	dynamic pressure, pounds per square inch	p	damping in roll
q^*	dimensionless dynamic pressure $\left(\frac{C_{L_{\alpha}} q (b'/2)^2 e_1 c_r^2 \cos \Lambda}{(GJ)_r}\right)$	R	reversal
$q^\dagger$	reduced dynamic pressure $\left(C_{L_{\alpha}} q \frac{b'}{2} c_r\right)$	R_0	reversal of unswept wing
$\bar{q}$	dimensionless dynamic pressure $\left(\frac{C_{L_{\alpha}} q (b'/2)^3 c_r \tan \Lambda}{(EI)_r \cos \Lambda}\right)$	r	at root or effective root
		rw	rigid wing
		sub	subsonic
		spr	supersonic
		w	wing exclusive of fuselage
		δ	due to (unit) aileron deflection
		Matrix notation:	
		$\{ \}$	column matrix
		$[\]$	row matrix
		$[\]$	square matrix
		$[\]$	diagonal matrix

[]'' double transpose of a matrix: first about the principal diagonal, then about the other diagonal

[1] unit matrix

$$[1_1'] = \begin{bmatrix} 0 & 0 & 0 & 0 & . & . \\ 1 & 0 & 0 & 0 & . & . \\ 1 & 0 & 0 & 0 & . & . \\ 1 & 0 & 0 & 0 & . & . \\ 1 & 0 & 0 & 0 & . & . \\ . & . & . & . & . & . \end{bmatrix}$$

DERIVATION OF THE METHOD

ASSUMPTIONS

The assumptions made in reference 1 are that all deformations and angles of attack are small and that the wing deformations either are known in the form of structural influence coefficients or can be calculated from simple beam theory in conjunction with rotations of a flexible root. In addition the assumption is made in the present report that the angle between the aileron and the wing is constant along the span of the aileron and that, in the absence of suitable aerodynamic influence coefficients, aeroelastic effects due to aileron deflection can be calculated on the basis of a modified strip theory.

AIR LOADS

The lift on a wing section of unit width parallel to the direction of flight may be expressed in terms of the loading coefficient cc_l/c_r as

$$\{l\} = qc_r \left\{ \frac{cc_l}{c_r} \right\} \quad (1)$$

In the case of a wing at zero angle of attack with ailerons deflected the lift may be considered to consist of two parts: one due to structural deformation and one due to aileron deflection. The loading coefficients for these two parts are best treated separately.

The part of the lift due to the antisymmetric structural twist can be written in terms of the local values of twist as

$$\left\{ \frac{cc_l}{c_r} \right\} = C_{L_\alpha} [Q_a] \{\alpha_s\} \quad (2)$$

in terms of suitable antisymmetric aerodynamic influence coefficients $[Q_a]$. Since no such coefficients are available at present, modified strip theory may be used, as in reference 1, with some saving in labor but at some sacrifice in accuracy. With this modified strip theory

$$\left\{ \frac{cc_l}{c_r} \right\} = C_{L_\alpha} \left[\frac{c}{c_r} \right] \{\alpha_s\} \quad (3)$$

where for subsonic speeds the approximate value of effective lift-curve slope C_{L_α} may be obtained from the equation

$$C_{L_\alpha} = c_{l_\alpha} \frac{A \cos \Lambda}{A + 4 \cos \Lambda}$$

and for supersonic speeds,

$$C_{L_\alpha} = \frac{4 \cos \Lambda_{c/2}}{\sqrt{M_0^2 \cos^2 \Lambda_{c/2} - 1}}$$

c_{l_α} being the lift-curve slope of the section perpendicular to the quarter-chord line at a Mach number equal to $M_0 \cos \Lambda$.

The lift due to aileron deflection should be calculated by a fairly accurate method (see references 2 and 3). This lift distribution may be expressed as

$$\begin{aligned} \left\{ \frac{cc_l}{c_r} \right\}_\delta &= \alpha_\delta \delta C_{L_\alpha} \left\{ \frac{cc_l}{c_r C_{L_\alpha}} \right\}_\delta \\ &= \alpha_\delta \delta C_{L_\alpha} \left[\frac{c}{c_r} \right] \left\{ \frac{c_l}{C_{L_\alpha}} \right\}_\delta \end{aligned}$$

where the coefficients $\left(\frac{c_l}{C_{L_\alpha}} \right)_\delta$ are the values of c_l calculated for a unit effective aileron deflection $\alpha_\delta \delta$ and divided by C_{L_α} .

The combined lift due to twist and aileron deflection is then

$$\{l\} = qc_r C_{L_\alpha} \left[\frac{c}{c_r} \right] \left\{ \alpha_s + \alpha_\delta \delta \left\{ \frac{c_l}{C_{L_\alpha}} \right\}_\delta \right\} \quad (4)$$

The torque per unit width of span is the product of the lift per unit width and the local moment arm. For the lift due to twist the moment arm is $e_1 c$; for the lift due to aileron deflection the moment arm is $-e_2 c$. (See fig. 1.) Consequently, the torque may be written as

$$\{t\} = qc_r^2 C_{L_\alpha} e_1 \left[\frac{e_1}{e_1} \left(\frac{c}{c_r} \right)^2 \right] \left\{ \alpha_s - \alpha_\delta \delta [\epsilon] \left\{ \frac{c_l}{C_{L_\alpha}} \right\}_\delta \right\} \quad (5)$$

where ϵ is the ratio of the moment arms e_2/e_1 .

THE AEROELASTIC EQUATION

Method employing stiffness curves.—The lifts and torques per unit width given in the preceding section can be integrated to obtain bending moments and accumulated torques about axes perpendicular and parallel to the plane of symmetry and, hence, about axes perpendicular and parallel to the elastic axis. Integration of these torques and moments yields the twists and local dihedrals, which can be combined to yield the desired angle of attack due to

FIGURE 1.—Definition of geometrical parameters used in the analysis.

structural deformation α_s . (See reference 1.) The resulting equation is

$$\{\alpha_s\} = \kappa q^* \left\{ [A] \{\alpha_s\} - \alpha_s \delta [\bar{A}] \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\} \right\} \quad (6)$$

where κ , the ratio of the effective to the actual wing lift-curve slope, is

$$\kappa = \frac{A + 2 \cos \Lambda}{A + 4 \cos \Lambda}$$

for subsonic flow and has a value of 1 for supersonic flow, q^* is the dimensionless dynamic pressure, $[A]$ is the aeroelastic matrix defined in reference 1 (for subsonic flow) as

$$[A] = \left[[I]'' \left[\frac{(GJ)_r}{GJ} \right] + \frac{w_e}{b'/2} (Q_{\alpha_T} - Q_{\alpha_M} \tan \Lambda) [1_1'] \right. \\ \left. + \frac{(GJ)_r}{(EI)_r} \tan^2 \Lambda [I]'' \left[\frac{(EI)_r}{EI} \right] [I'] \left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right] \right. \\ \left. - \left[k [I]'' \left[\frac{(EI)_r}{EI} \right] - \frac{w_e}{b'/2} \frac{b'/2}{e_{1r} c_r \cos^2 \Lambda} Q_{\alpha_M} [1_1'] \right] [II'] \left[\frac{c}{c_r} \right] \right] \quad (7)$$

and $[\bar{A}]$ is an auxiliary aeroelastic matrix defined (for subsonic flow) by

$$[\bar{A}] = \left[[I]'' \left[\frac{(GJ)_r}{GJ} \right] + \frac{w_e}{b'/2} (Q_{\alpha_T} - Q_{\alpha_M} \tan \Lambda) [1_1'] \right. \\ \left. + \frac{(GJ)_r}{(EI)_r} \tan^2 \Lambda [I]'' \left[\frac{(EI)_r}{EI} \right] [I'] \left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right] [\epsilon] \right. \\ \left. + \left[k [I]'' \left[\frac{(EI)_r}{EI} \right] - \frac{w_e}{b'/2} \frac{b'/2}{e_{1r} c_r \cos^2 \Lambda} Q_{\alpha_M} [1_1'] \right] [II'] \left[\frac{c}{c_r} \right] \right] \quad (8)$$

For supersonic flow, matrices $[I]$ and $[II]$ are used instead of matrices $[I']$ and $[II']$, provided that the decrease in lift

at the tip is known; otherwise, matrices $[I']$ and $[II']$ may be used in supersonic flow also as a fair approximation.

Method employing structural influence coefficients.—If the angle-of-attack changes due to unit concentrated normal loads and torques $[\Phi_P]$ and $[\Phi_T]$ have been determined in static tests of the actual structure or calculated by a method such as that of reference 4, they may be used in an aeroelastic analysis in the manner indicated in reference 1. The pertinent aeroelastic equation for the lateral-control problem is

$$\{\alpha_s\} = \kappa q^* \left\{ [A'] \{\alpha_s\} - \alpha_s \delta [\bar{A}'] \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\} \right\} \quad (9)$$

where $[A']$ is the aeroelastic matrix defined in reference 1 as

$$[A'] = \left[e_{1r} c_r [\Phi_T] [C_3'] \left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right] + [\Phi_P] [C_4'] \left[\frac{c}{c_r} \right] \right] \quad (10)$$

$[\bar{A}']$ is an auxiliary aeroelastic matrix defined by

$$[\bar{A}'] = e_{1r} c_r [\Phi_T] [C_3'] \left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right] [\epsilon] - [\Phi_P] [C_4'] \left[\frac{c}{c_r} \right] \quad (11)$$

q^* is the reduced dynamic pressure defined by

$$q^* = C_{L_{\alpha}} q \frac{b'}{2} c_r$$

and the load-conversion matrices $[C_3']$ and $[C_4']$ are defined and given in reference 1.

SOLUTION OF THE AEROELASTIC EQUATION

Calculation of the control effectiveness.—The aerodynamic loading corresponding to a given aileron deflection at a given dynamic pressure can be obtained by writing equation (6) or equation (9) in the form

$$[[1] - \kappa q^* [A]] \{\alpha_s\} = -\kappa q^* \alpha_s \delta [\bar{A}] \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\} \quad (12)$$

Once the right-hand side of equation (12) is evaluated it may be regarded as a set of knowns which in conjunction with the coefficients of the matrix $[[1] - \kappa q^* [A]]$ permits a solution for the unknowns $\{\alpha_s\}$. The loading corresponding to $\{\alpha_s\}$ may then be obtained from equation (4) and hence the net rolling moment due to aileron deflection and the resulting wing deformations:

$$\text{Rolling moment} = 2 \left(\frac{b'}{2} \right)^2 [II'_0] \{\alpha_s\} \quad (13)$$

where

$$[II'_0] = [II'_1] + \frac{w}{b'} [I'_1] \quad (14)$$

As indicated in reference 1, the solution of the set of simultaneous equations represented by equation (12) may be carried out by any conventional method of solving simultaneous equations or by an iteration procedure; the choice of method depending primarily on the preference of the computer.

Calculation of the aileron reversal speed.—The aileron reversal speed can be obtained by calculating the rolling moment due to aileron deflection, as indicated in the

preceding paragraph, and plotting it against the speed or dynamic pressure. The value or values of the speed or dynamic pressure for which the rolling moment is zero constitute the aileron reversal speeds or dynamic pressures. However, a more direct procedure, similar to that used to find the divergence speed in reference 1, can be derived as follows.

The term $\alpha_s \delta \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s$ in equation (12) can be expressed in terms of $\{\alpha_s\}$ by means of equations (4) and (13) since at the aileron-reversal condition the rolling moment is equal to zero. Hence,

$$[II']_0 \left[\frac{c}{c_r} \right] \left\{ \{\alpha_s\} + \alpha_s \delta \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s \right\} = 0$$

or

$$\alpha_s \delta = - \frac{[II']_0 \left[\frac{c}{c_r} \right] \{\alpha_s\}}{[II']_0 \left[\frac{c}{c_r} \right] \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s}$$

Multiplying both sides of this equation by $\left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s$ yields

$$\alpha_s \delta \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s = - \frac{1}{g} \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s [II']_0 \left[\frac{c}{c_r} \right] \{\alpha_s\} \quad (15)$$

where

$$g = [II']_0 \left[\frac{c}{c_r} \right] \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s \quad (16)$$

Substitution of equation (15) in equation (12) yields

$$\{\alpha_s\} = \kappa q^* [A_R] \{\alpha_s\} \quad (17)$$

where the aileron-reversal matrix $[A_R]$ is defined by

$$[A_R] = [A] + \frac{1}{g} [A] \left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_s [II']_0 \left[\frac{c}{c_r} \right] \quad (18)$$

The value of the dimensionless dynamic pressure κq^* at reversal can be found by iterating equation (17) or by expanding the determinant of the matrix $[1] - \kappa q^* [A_R]$ and setting the resulting polynomial in κq^* equal to 0, as described in reference 1.

APPLICATION OF THE METHOD

SELECTION OF THE PARAMETERS

The geometric and structural parameters used in the calculation of the lateral-control effectiveness and related aerodynamic properties of a wing are the same as those used in the calculations of the aerodynamic loading described in reference 1. If the root-rotation constants are different for symmetric and antisymmetric loadings, those for antisymmetric loadings should be used for calculating the $[A]$ matrix used in this report. Similarly, the section lift-curve slope, wing lift-curve slopes, and local aerodynamic-center values are chosen for the Mach number of interest, as described in reference 1, except for the calculation of the aileron reversal speed, as discussed in the section entitled "Calculation of the Aileron Reversal Speed."

The values of α_s and cp_s are best obtained from experimental section data at the appropriate Mach number $M_0 \cos \Lambda$. These values, in terms of commonly available quantities, are

$$\alpha_s = \frac{\frac{dc_l}{d\delta}}{\frac{dc_l}{d\alpha}}$$

and

$$cp_s = 0.25 - \frac{\frac{dc_{m_{c/4}}}{d\delta}}{\frac{dc_l}{d\delta}}$$

Theoretical thin-airfoil values of these parameters are given in figure 2 for subsonic and supersonic speeds. Insufficient information exists at present to permit an accurate correction of these data for finite-span effects in all cases. In a qualitative sense, the section value of α_s is known to be a useful approximation to the actual value required in the calculations of this report, except for wings of very low aspect ratio, for which the value of α_s tends to be somewhat larger than the section value.

The values of cp_s on a wing tend to be further rearward than the values obtained from section data at subsonic speeds. The finite-span values may be estimated by calculating lift distributions for a given aileron deflection both by unmodified strip theory and by a rational finite-span method, such as that of reference 2 or of reference 3; if the local lift given by strip theory is assumed to act at the section value of cp_s , and if the difference in the lifts given by the two theories is assumed to act at the local aerodynamic center, the chordwise location of the resultant of these two forces may be considered to be the three-dimensional value of cp_s . On the basis of this approximation $e_2 = -e_1$ at all points on the wing not covered by the aileron.

FIGURE 2.—Theoretical thin-airfoil values of the aileron force parameters.

The values of $\left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_i$ required in this report may also be obtained for subsonic speeds by the methods of references 2 or 3 by calculating spanwise lift distributions in the form $\frac{cc_l}{2b}$ for $\alpha\delta=1$ and multiplying the results by $\frac{2b}{cC_{L_{\alpha_e}}}$. A simpler but less accurate way of estimating these values consists in using the modified strip theory, which is also used in this report for the calculation of the lift due to structural deformations, until suitable aerodynamic influence coefficients are available. This approximation implies that the elements of $\left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_i$ are 0 for stations not covered by the aileron and 1 for stations covered by the aileron. However, in order to take into account the location of the inboard and outboard extremities of the aileron with the relatively few stations used in the analysis, equivalent values of $\alpha\delta$ have to be used. These values, referred to as equivalent δ values, are given in figure 3. They are intended to give a rounded-off distribution of $\left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}_i$ which has approximately the same area and the same moment about the root as the unmodified strip-theory distribution. The equivalent δ values of figure 3 pertain to actual values of $\alpha\delta$ equal to 1; they apply to ailerons which extend from $\frac{\eta_i}{b'/2}$ to the tip but can be combined to apply to any aileron configuration. Several examples are listed in the following table for the six-point method, the values of $\alpha\delta$ being 1 and the equivalent values being read from figure 3(a) as 0.716 for $\frac{\eta_i}{b'/2}=0.55$ and as 0.293 for $\frac{\eta_i}{b'/2}=0.95$:

Aileron ends	Case 1	Case 2	Case 3	Case 4	Case 5
$\frac{\eta_i}{b'/2}$	0.55	0.95	0.55	0	0
$\frac{\eta_o}{b'/2}$	1.00	1.00	.95	1.00	.55
$\frac{\eta}{b'/2}$	$\left\{ \frac{c_l}{C_{L_{\alpha_e}}} \right\}$ according to modified strip theory				
	Case 1	Case 2	Case 3	Case 4	Case 5
0	0	0	0	1	1
.20	0	0	0	1	1
.40	0	0	0	1	1
.60	.716	0	.716	1	.284
.80	1	0	1	1	0
.90	1	.293	.707	1	0

The values of case 3 are obtained from those of cases 1 and 2 and the values for case 5, from the ones of cases 1 and 4.

CALCULATION OF THE MATRICES

A brief introduction to matrix methods is given in the appendix of reference 1; a fuller treatment is given in reference 5. The numerical constants required in the method of this report are given in reference 1 and in the present report for 6-point and 10-point solutions. The elements of the matrices $[I]$ and $[I']$ are given in table I and those of the matrices $[II]$ and $[II']$, in table II. The matrix $[I]''$ is essentially the double transpose of the matrix $[I]$ and its elements are given in table III. If the structural influence-coefficient method is used, the required matrices $[C_3']$ and $[C_4']$ may be obtained from reference 1.

The matrix $[A]$ is calculated as described in reference 1 and, if desired, by means of the computing forms given in reference 1. The steps in the computation may be summarized as follows:

Step	Operation
①	$[I]'' \left[\frac{(GJ)_r}{GJ} \right]$
②	$[I]'' \left[\frac{(EI)_r}{EI} \right]$
③	$\frac{(GJ)_r}{(EI)_r} \tan^2 \Lambda$ [②]
④	$\frac{w_e}{b'/2} (Q_{\alpha_T} - Q_{\alpha_M} \tan \Lambda)$ [①']
⑤	[①]+[③]+[④]
⑥	$[I'] \left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right]_{sub}$
⑦	[⑤][⑥]
⑧	k [②]
⑨	$\frac{w_e}{b'/2} \frac{b'/2}{e_{1r} c_r \cos^2 \Lambda} Q_{\alpha_M}$ [①']
⑩	[⑧]-[⑨]
⑪	$[II'] \left[\frac{c}{c_r} \right]$
⑫	[⑩][⑪]
⑬	$[A] = [⑦] - [⑫]$

where the notation [⑦], for instance, refers to the matrix calculated in step 7. For supersonic speeds four additional steps are required:

⑥a	$[I] \left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right]_{spr}$
⑦a	[⑤] [⑥a]
⑫a	$\frac{(e_{1r})_{sub}}{(e_{1r})_{spr}}$ [⑫]
⑬a	$[A] = [⑦a] - [⑫a]$

(a) Six-point method.
(b) Ten-point method.
FIGURE 3.—Equivalent values of δ .

To proceed with the calculation of lateral control and of the aileron reversal speed, the auxiliary aeroelastic and the aileron-reversal matrices are then calculated as shown in table IV; the numbering of the steps indicated in the upper left corner of each block is a continuation of the numbering of the steps required to calculate the matrix $[A]$. The auxiliary aeroelastic matrix is obtained in step 15 and the aileron-reversal matrix, in step 20. The value of g required in step 16 is obtained by *post*multiplying the row $[II'_0] \left[\frac{c}{c_r} \right]$ obtained in the step immediately above step 16 by the column $\left\{ \frac{c_i}{C_{L_{\alpha_e}} \delta} \right\}$. On the other hand, the square matrix of step 18 is obtained by *pre*multiplying the row matrix $[\textcircled{17}]$, which is the same row matrix $[II'_0] \left[\frac{c}{c_r} \right]$ multiplied by $\frac{1}{g}$, by the column $\left\{ \frac{c_i}{C_{L_{\alpha_e}} \delta} \right\}$.

A separate set of calculations from step 14 to step 20, inclusive, has to be performed for subsonic and supersonic speeds; the steps for supersonic speeds can be labeled steps 14a to 20a to follow the pattern set in reference 1. For a 10-point solution, forms similar to those of table IV can easily be drawn up. For the influence-coefficient method a set of computing instructions and computing forms can be based on equations (10) and (11) in the same way as the instructions and forms discussed in this section are based on equations (7), (8), and (18).

Special cases arise when any or all of the values of e_1 or of e_2 are zero. If only e_{1r} is zero, the value of e_1 at some other point can be used as a reference throughout the analysis and the parameter q^* can be redefined accordingly. The first column of the matrix $[\textcircled{19}]$ is calculated in this case by multiplying the first column of the matrix $[\textcircled{5}] [I']$ by the ratio of the value e_2 to the reference value of e_1 . Similarly, if some other value of e_1 is zero, say the n th along the span, e_{1r} is used as a reference but the n th column of $[\textcircled{19}]$ is calculated by multiplying the n th column of the matrix $[\textcircled{5}] [I']$ by $\frac{e_{2n}}{e_{1r}} \left(\frac{c_n}{c_r} \right)^2$, where e_{2n} and c_n are the values of e_2 and c at the n th station.

If e_1 is zero along the entire span, some of the computing instructions given in this report, as well as the ones given in reference 1, must be modified somewhat. In table VI (a) of reference 1 the matrix $\left[\frac{e_2}{e_{2r}} \left(\frac{c}{c_r} \right)^2 \right]$ can be entered in the space provided for the $\left[\frac{e_1}{e_{1r}} \left(\frac{c}{c_r} \right)^2 \right]$ matrix. Some of the instructions of table VI(b) of reference 1 and table IV of this report are then modified as follows:

Step 6	$[I'] \left[\frac{e_2}{e_{2r}} \left(\frac{c}{c_r} \right)^2 \right]$
Step 9	$\frac{(EI)_r}{(GJ)_r} \frac{w_e}{b'/2} \frac{Q_{\alpha_M}}{\tan \Lambda} [1,']$
Step 10	$[\textcircled{9}] - [\textcircled{2}]$

Step 11	As is
Step 12	Omit
Step 13	$[A]_{e_1=0} = [\textcircled{10}] [\textcircled{11}]$
Step 14	$\frac{e_{2r} c_r \cos^2 \Lambda}{b'/2} \frac{(EI)_r}{(GJ)_r} \frac{1}{\tan \Lambda} [\textcircled{7}]$
Step 15	$[\bar{A}] = [\textcircled{14}] - [\textcircled{13}]$

All other instructions are unaffected.

If e_2 is zero along the span, table IV of this report may be modified as follows:

Step 15	$[\bar{A}] = [\textcircled{12}]$
---------	----------------------------------

Step 14 may be omitted in this case; all other steps in table IV are unaffected.

Similar modifications must also be made if the influence-coefficient method is used.

CALCULATION OF THE AILERON REVERSAL SPEED

The matrix $[A_R]$ is iterated in table V(a) to calculate the critical value of the parameter κq^* and hence the critical speed. The calculation has to be performed once for subsonic speeds and, if the airplane is to fly at transonic and supersonic speeds, once for supersonic speeds. From these critical values, from the definition of the parameters κ and q^* , and from the lift-curve slope the dynamic pressure required for aileron reversal q_R may be calculated and plotted as a function of Mach number. If the actual dynamic pressure for the altitudes of interest is also plotted on the same chart, the lowest intersection of the reversal with a true-dynamic-pressure line will give the reversal Mach number and dynamic pressure at the altitude of the true-dynamic-pressure line.

The matrices $[A_R]$ calculated for the special cases mentioned in the preceding section do not all yield the critical value of the parameter κq^* . When the value of e_1 is zero at the root, the critical value of the parameter κq^* based on the reference value of e_1 will be obtained. If e_1 is zero at some other point along the span or if e_2 is zero along the entire span, critical values of the parameter κq^* will be obtained. In the case where e_1 is zero along the entire span, iteration of the matrix $[A_R]$ calculated by following the instructions of the preceding section will yield the value of the parameter $\kappa \bar{q}$ at reversal.

In some of these special cases, and possibly in other cases as well, the iteration procedure may not converge. In those cases the lowest value of the parameters $(\kappa q^*)_R$ or $(\kappa \bar{q})_R$ is imaginary, so that there is no physical reversal speed corresponding to this value, and the wing under consideration is likely to be safe against reversal (in the speed range under consideration). If the lowest value of the parameter κq^* has the sign opposite to that of the value of e_{1r} (or the other value of e_1 used as a reference) or if the critical value of $\kappa \bar{q}$ has the sign opposite to that of the sweep angle Λ , the reversal dynamic pressure is negative. In that case the wing also is likely to be safe against reversal, since a negative dynamic pressure cannot be obtained at any real speed.

However, if the wing is to operate at dynamic pressures which correspond to values of κq^* or $\kappa \bar{q}$ much larger than the absolute values of the critical values obtained by iteration, the next higher eigenvalues of the aileron-reversal matrix may have to be calculated by a method such as that given in reference 5, page 143. If the next higher eigenvalue is real and of appropriate sign, it defines the critical aileron reversal speed.

Instead of iterating the matrix $[A_R]$ to calculate $(\kappa q^*)_R$ the determinant of the matrix $[1] - \kappa q^*[A_R]$ may be expanded and equated to zero, as noted in reference 1. The result is an equation of the type

$$C_n(\kappa q^*)^n + C_{n-1}(\kappa q^*)^{n-1} + \dots + C_1(\kappa q^*) + 1 = 0$$

where n is the order of the matrix—that is, 6 or 10 in the case of a 6-point or 10-point solution, respectively. Solution of this equation yields n values of κq^* ; the lowest real value with the appropriate sign is the one that defines the critical reversal speed. Instead of actually expanding the determinant, however, the coefficients $C_1, C_2, \dots, C_n$ can be obtained in terms of the traces of the powers of the matrix $[A_R]$, the trace of a matrix being the sum of the elements on its principal diagonal, and the n th power of the matrix $[A_R]$ being the matrix obtained by multiplying $[A_R]$ by itself $n-1$ times. If s_m is the trace of $[A_R]^m$, then

$$C_1 = -s_1$$

$$C_2 = -\frac{1}{2}(C_1 s_1 + s_2)$$

$$C_3 = -\frac{1}{3}(C_2 s_1 + C_1 s_2 + s_3)$$

$$\dots$$

$$C_n = -\frac{1}{n}(C_{n-1}s_1 + C_{n-2}s_2 + \dots + C_1s_{n-1} + s_n)$$

Unless certain types of automatic computing machinery are available, the iteration procedure is generally preferable to the procedure based on the expansion of the determinant.

CALCULATION OF CONTROL POWER AND MANEUVERABILITY

The calculation of the twist distribution for a given aileron deflection may be carried out in table V (b), which is similar to table VI (b) of reference 1. The matrix $[1] - \kappa q^*[A]$ is entered at the left, and the column $\left\{ \frac{c_i}{C_{L_{\alpha_e}}} \right\}$ is entered at the right. This column is premultiplied by the $[\bar{A}]$ matrix obtained in step 15 or step 15a and is entered in the second column at the right, which in turn is multiplied by $-\kappa q^*$ to yield the third column. The simultaneous equations with the coefficients at the left and the knowns at the right (the third column) are then solved for the unknown α_s values. If preferred, an iterative solution of the type discussed in reference 1 may be used instead of Crout's method (reference 6) for which table V is set up. A computing form similar to that of table VII (c) of reference 1 may be used for this purpose.

If the same values of κq^* are selected as were used in the calculation of the aerodynamic loading by the method of reference 1, the $[1] - \kappa q^*[A]$ matrix is already available. If, in addition, Crout's method of solving simultaneous equations has been used to solve the simultaneous equations, part of the auxiliary matrix is also available so that calculation of the α_s values for the aileron loading requires very little time. However, the iterative solution does not have this advantage.

In some of the special cases discussed in the preceding sections, care must be taken to use the proper parameters in conjunction with the matrices calculated for these special cases. In the case where e_{1r} is zero, the values of κq^* must be based on the reference value of e_1 selected in calculating the matrix; in the case where e_1 is zero along the entire span, the parameter $\kappa \bar{q}$ must be used instead of κq^* in table V (b).

The resulting α_s values may be added algebraically to the values of $\left\{ \frac{c_i}{C_{L_{\alpha_e}}} \right\}_{\delta}$, multiplied by $\frac{c_r}{\bar{c}}$ and $\left[\frac{c}{c_r} \right]$ as indicated in steps 4, 5, and 6 of table V(b), and plotted over the span

to yield the net aerodynamic load distribution $\left\{ \frac{cc_i}{\bar{c}C_{L_{\alpha_e}}} \right\}_{\delta_{fw}}$ which pertains to a unit value of $\alpha_s \delta$ on the flexible wing. The rolling-moment coefficient due to this forcing loading (over both wings) may be obtained from a dimensionless form of equation (13)

$$C_{l_w} = \frac{1}{2} C_{L_{\alpha_e}} \left(\frac{b'}{b} \right)^2 |II'|_{01} \left\{ \frac{cc_i}{\bar{c}C_{L_{\alpha_e}}} \right\}_{\delta_{fw}} \quad (19)$$

This coefficient, which is a direct measure of the rolling power, is seen to be dependent only on q/q_D (except for the factor $C_{L_{\alpha_e}}$) since $\frac{q}{q_D} = \frac{\kappa q^*}{(\kappa q^*)_D}$ and $(\kappa q^*)_D$ is constant for a given speed range.

The rolling maneuverability depends not only on the rolling power but also on the damping in roll. The rate of roll per unit aileron deflection (measured in a plane parallel to the plane of symmetry) is given by

$$\left(\frac{pb}{2V} \right)_{\delta=1} = \alpha_s \frac{C_{l_b}}{C_{l_p}} \quad (20)$$

where C_{l_b} is the forcing coefficient calculated from equation (19) (if the contributions of the pressures on the fuselage are neglected) and C_{l_p} is the damping coefficient calculated from equation (19) with a column of values of $\left\{ \frac{cc_i}{\bar{c}C_{L_{\alpha_e}}} \right\}$ calculated

by the method of reference 1 for a case where $\alpha_s = \frac{y}{b/2}$. If modified strip theory is used, the desired column is

$$\left\{ \frac{cc_i}{\bar{c}C_{L_{\alpha_e}}} \right\} = \frac{c_r}{\bar{c}} \left[\frac{c}{c_r} \right] \{ \{ \alpha_s \} + \{ \alpha_e \} \}$$

where α_e is the structural deformation associated with the given values of α_s .

ILLUSTRATIVE EXAMPLE

The method described in the preceding sections has been used to analyze the lateral maneuverability of the wing considered in the illustrative example of reference 1. The required additional parameters of this wing are presented in table VI (a), which follows the form of table IV (a). Modified strip theory has been used for calculating $\left\{ \frac{c_l}{C_{L_{\alpha_e}} } \right\}_\delta$. The equivalent value of δ at the station $\frac{\eta}{b'/2} = 0.4$ is obtained from figure 3 for the given values of $\frac{\eta_i}{b'/2}$ and $\frac{\eta_o}{b'/2}$. The auxiliary aeroelastic matrix for the subsonic case has been calculated by following the form of table IV(b); the resulting matrix is shown in table VI (b).

The aileron-reversal matrix for the subsonic case is calculated by means of the form of table IV (c). Several of the steps, as well as the result, are shown in table VI (c) for the subsonic case. In these calculations the contribution of the matrix $[I'_1]$ to the matrix $[II'_0]$ has been neglected, so that the matrix $[II'_1]$ has been used instead of the matrix $[II'_0]$, a procedure which is not recommended in general. Iteration of the aileron-reversal matrix (by means of the form of table V(a) or otherwise) yields a value of $(\kappa q^*)_R = 2.364$. A similar calculation for supersonic speeds yields a value of $(\kappa q^*)_R = 0.1280$. From these two values and the definition of the parameters κ and q^* the dynamic pressure required for reversal has been calculated and is plotted against Mach number in figure 4. Also shown in figure 4 for comparison are the dynamic pressures required for divergence as well as the actual dynamic pressures at sea level and at an altitude of 25,000 feet. Where the dynamic pressure required for reversal is less than the actual dynamic pressure, the aileron control is reversed. For the example wing, reversal is likely to occur at a Mach number of approximately 1.3 at sea level.

The aerodynamic loading due to aileron deflection has been calculated by means of the form of table V(b). For the subsonic case and for $\kappa q^* = 0.552$ the $[[1] - \kappa q^*[A]]$ matrix is that shown in table X(b) of reference 1. The three columns to be entered at the right of table V(b), as well as the four columns obtained at the bottom of table V(b), are as follows:

①	②	③	⑥	⑤	④	Final matrix
$\left\{ \frac{c_l}{C_{L_{\alpha_e}} } \right\}$	$[A] \{ \textcircled{1} \}$	$-\kappa q^* \{ \textcircled{2} \}$	$\frac{c_r}{\bar{c}} \{ \textcircled{6} \}$	$\left[\frac{c}{c_r} \right] \{ \textcircled{4} \}$	$\{ \textcircled{1} \} + \{ \alpha_s \}$	$\{ \alpha_s \}$

FIGURE 4.—Effect of Mach number on the divergence and aileron-reversal dynamic pressures of the example wing.

The lift distribution due to aileron deflection

$$\left\{ \frac{cc_l}{\bar{c}C_{L_{\alpha_e}} } \right\}_\delta = \frac{c_r}{\bar{c}} \left[\frac{c}{c_r} \right] \left\{ \frac{c_l}{C_{L_{\alpha_e}} } \right\}_\delta$$

obtained by using the modified strip-theory values of $\left\{ \frac{c_l}{C_{L_{\alpha_e}} } \right\}_\delta$ is plotted in figure 5. For the flexible wing the lift distributions due to the calculated twist distributions, such as the one shown in the next to the last column of the foregoing tabulation, must be added algebraically to the lift distribution due to aileron deflection. This addition is best performed by first plotting the lift distributions due to twist

Case	q/q_D	q/q_R	Condition
1	0	0	Subsonic
2	-0.25	0.234	Subsonic
3	-0.50	0.467	Subsonic
4	-0.50	0.577	Supersonic
5	-1.00	1.154	Supersonic

FIGURE 5.—Loading of example wing with aileron deflected.

separately and then adding them point for point to the lift distribution due to aileron deflection. The net distributions obtained in this manner for several cases are shown in figure 5. The distribution for case 5 (supersonic speeds, $\frac{q}{q_D} = -1.00$) indicates that the wing is operating at a speed above its reversal speed; from the given values of q^*_D and q^*_R the dynamic pressure for the case of $\frac{q}{q_D} = -1.00$ can be seen to exceed by 15.4 percent the dynamic pressure required for aileron reversal.

The rolling-moment coefficient is obtained from equation (19) or by adding the moments corresponding to the aileron-distribution curve and the twist curve algebraically. (As stated previously, the contribution of $[I'_1]$ to $[II'_0]$ has been neglected in these calculations.) The ratio of the flexible-wing rolling-moment coefficient obtained in this manner to the corresponding rigid-wing rolling-moment coefficient is plotted in figure 6 (a) against the ratio $-q/q_D$; for the rigid wing the value of C_{l_i} at subsonic speeds is

$$(C_{l_i})_{rw} = 0.070 C_{L_{\alpha_e}}$$

and at supersonic speeds is

$$(C_{l_i})_{rw} = 0.026 C_{L_{\alpha_e}}$$

The lateral maneuverability is calculated by means of equation (20) with the damping coefficients calculated in reference

FIGURE 6.—Control power and effectiveness of example wing.

1 and is also plotted in figure 6 (a) as a fraction of the rigid-wing value, which at subsonic speeds is

$$\left(\frac{pb}{2V}\right)_{rw} = 0.634$$

and at supersonic speeds is

$$\left(\frac{pb}{2V}\right)_{rw} = 0.232$$

Both the maneuverability and the control power become zero at a value of $\frac{q}{q_D} = -0.87$, which is the ratio of the reversal to the divergence dynamic pressure at supersonic speeds, as is shown in figure 4.

Since the ratio q/q_D has been determined as a function of altitude and Mach number in figure 4, the parameters of figure 6 (a) can be plotted as functions of altitude and Mach number, as has been done in figure 6 (b). The maneuverability and, to a lesser extent, the control power are relatively low at supersonic speeds, particularly at low altitudes. Since at high speeds even a small value of $pb/2V$ implies a fairly large

value of the rate of roll p , this situation is not necessarily alarming. The wing in question should have adequate control at all speeds for altitudes greater than about 20,000 feet.

DISCUSSION

The method of this report is based in essence on a numerical integration by means of matrices of the differential equations of structural equilibrium. The actual stiffness distributions, root rotations, and the lift and pitching-moment distributions of the undeformed wing can be taken into account as accurately as they are known. The commonly made simplification of treating the wing as an aggregate of constant-chord segments with all flexibility concentrated at the ends and all forces at the midpoint of the segments is not resorted to in this report. No time-consuming graphical integrations nor trial and error procedures are used. The aileron reversal speed is calculated by means of an iteration, but each cycle of this iteration consists of a single matrix multiplication so that the entire procedure is straightforward in application, and usually the results converge rapidly. If preferred, the iteration procedure can be replaced by an expansion of the determinant of the matrix $[[1] - \kappa q^*[A_R]]$, as outlined in this report.

The purpose of this section is to discuss the assumptions and limitations of the method of this report and to indicate the effect of certain design variables on the aileron reversal speed by means of the results of a few calculations for the example wing and some others related to it.

ASSUMPTIONS AND LIMITATIONS OF THE METHOD

The discussion of the aerodynamic and structural assumptions in reference 1 is also pertinent to the analysis of this report. This discussion may be summarized as follows: All angles of attack, structural deformations, and control deflections must be sufficiently small to give rise only to linear aerodynamic and structural forces. When structural influence coefficients are used, no further assumptions are necessary concerning the structural deformations; when the stiffness curves are used, elementary beam theory as corrected by root rotations must be applicable. If elementary beam theory is inapplicable—that is, if shear deformations, shear lag, and bending-torsion interaction cannot be neglected—a more refined method than elementary beam theory, such as the method of reference 4, can be used to calculate structural influence coefficients which can be used in the method of the present report. When suitable aerodynamic influence coefficients are available, no further assumptions need be made concerning the aerodynamic forces; if no such coefficients are available, the assumption must be made that modified strip theory is sufficiently accurate to calculate the aeroelastic effects of interest.

In the present report additional aerodynamic assumptions must be made, primarily, because although accurate aerodynamic information can be used in the method of this report such information is not available in many instances. For instance, no suitable aerodynamic influence coefficients are available as yet for antisymmetric lift distributions so that modified strip theory has to be used for the lift due to

structural deformation. For the lift due to aileron deflection, which is used in the form of the coefficients $\left(\frac{c_l}{C_{L\alpha_e}}\right)_\delta$, the best

available information should be used; for unswept wings of moderate or high aspect ratio the method of reference 2 gives accurate results, and for swept wings or wings of low aspect ratio the method of reference 3, with certain modifications explained in reference 6, may be used to calculate the desired coefficients. However, information concerning the parameters α_δ and cp_δ for wings of finite span is very meager; the suggested means of estimating them give results which must be used with some caution. If experimental results are available for these parameters, they can, of course, be used in this method.

Modified strip theory should not in general be used to calculate the coefficients $\left(\frac{c_l}{C_{L\alpha_e}}\right)_\delta$, as was done in the illustra-

tive example. If it is desired to use this approximation, the equivalent δ values of figure 3 may be used to obtain a suitable fairing of the lift-distribution curve at the aileron ends. However, these equivalent values are premised on the use of the $[I']$ and $[II']$ matrices and should not be employed for any other purpose than that indicated herein.

Two additional structural assumptions are also made in this report. In the first place, the angle δ between the wing and the aileron is assumed to be constant along the span. This assumption appears to have been made in almost all of the published investigations into the problem of lateral-control reversal and appears to have yielded satisfactory results; the shorter the aileron and the greater the number of points at which the aileron is supported and at which its hinge moment is taken out, the more nearly true is the assumption. Also, the control linkage is assumed to be stiff so that the aileron angle for a given stick displacement is independent of the dynamic pressure. However, in order to account for the control-linkage deflection, it is necessary only to calculate the ratio of the true aileron angle at a given dynamic pressure to that at zero dynamic pressure for the same stick position. The calculated control moment and maneuverability must then be reduced by this factor to get values of these quantities for a given stick displacement. Since deformations of the control linkage only affect the aileron effectiveness, they have no bearing on the reversal speed. On the other hand, these deformations may lead to aileron divergence for wings with heavily overbalanced ailerons. This problem, as well as the problem of wing-aileron divergence, has not been considered in the present analysis.

The fuselage and tail do not contribute any appreciable amounts to either the control or the damping moment so that their effects may ordinarily be neglected for the purpose of lateral-control calculations. Similarly, the effect of wing camber does not enter into the problem, because the only important effect of camber is to give the flexible wing a symmetrical lift distribution if it is set at the angle of attack which would give zero lift for the rigid wing; this symmetrical lift distribution has no effect on the lateral-control problem.

As in reference 1, the effects of the inertia loading on the aerodynamic loading have not been considered explicitly in the analysis of this report. As pointed out in reference 1, however, the structural deformations due to the inertia loading may be calculated conveniently by means of the integrating matrices and then be considered as part of the geometrical angles of attack. This procedure may be applied in the case of a rolling wing to determine the change in rolling moment for a unit rolling acceleration at any given Mach number and dynamic pressure. This rolling moment must be taken into account in estimating the rolling accelerations due to a given forcing moment at any time before the steady-roll condition is reached.

At transonic speeds there is considerable uncertainty in the aerodynamic parameters. The control power is directly proportional to the value of the parameter $c_{l_\delta} = \frac{dc_l}{d\delta}$, which may be quite low in the transonic region

due to the fact that the aileron is located in a region of separated flow. The method of this report is applicable to this case if the value of c_{l_δ} is known for the rigid wing and if the aerodynamic forces due to aileron deflection and due to twist can be superimposed linearly. If, for instance, the decrease in this parameter due to flow separation is 40 percent at a given Mach number and if the loss in control power due to wing flexibility amounts to 20 percent, then the total loss is 52 percent. However, the loss in maneuverability due to the decrease in c_{l_δ} may be much less than the loss in control power, since a decrease in c_{l_δ} is usually accompanied by a decrease in c_{l_α} and $C_{L_{\alpha_e}}$ and hence in the coefficient of damping in roll.

Should the value of the parameter c_{l_δ} decrease to zero or reverse, aileron reversal will occur. This type of reversal is altogether different from the type of reversal discussed in this report since it is due entirely to aerodynamic action, whereas the reversal of concern in this report is due to aeroelastic action. Both types of reversal are largely independent of each other; aerodynamic reversal is likely to occur at a given Mach number regardless of the stiffness of the wing, whereas aeroelastic reversal will occur ordinarily at a different speed which is unaffected by the aerodynamic effectiveness.

EFFECTS OF SOME DESIGN VARIABLES ON THE AILERON REVERSAL SPEED

Some general effects of sweep and of the moment arms e_1 and e_2 on the aeroelastic reversal speed may be of interest. The ratio of the reversal parameter $(\kappa q^*)_R$ of a given wing to that of the unswept wing obtained by rotating the given wing $(\kappa q^*)_{R_0}$ is shown in figure 7 (a) plotted against a function of the sweep angle for subsonic and supersonic speeds; the two curves were obtained by considering the wing of the illustrative example to be rotated in such a manner as to keep the parameters $\frac{e_1 c_r \cos^2 \Lambda}{b'/2}$ and $\frac{(EI)_r}{(GJ)_r}$ as well as the chord, stiffness, and moment-arm distributions e_1 and e_2 constant.

(a) Effect of sweep on reversal parameter $(\kappa q^*)_R$.
(b) Effect of moment-arm ratio ϵ on reversal parameter $(\kappa q^*)_R$ for unswept wings.
FIGURE 7.—Effects of sweep and moment-arm ratio on reversal speed.

Both sweepback and sweepforward apparently tend to decrease the reversal parameter and hence the reversal speed. At supersonic speeds or, more specifically, at small values of the parameter $\frac{e_2 c_r \cos^2 \Lambda}{b'/2} \sqrt{\frac{(EI)_r}{(GJ)_r}}$ the reversal speed for the sweptforward wing is somewhat lower than that of the sweptback wing; whereas at higher values of the parameter the variation of the reversal speed with the sweep parameter $\tan \Lambda \sqrt{\frac{(GJ)_r}{(EI)_r}}$ is more nearly symmetrical with respect to the zero-sweep case. There are some indications that this behavior is not typical of all wings but rather is due to the fairly large variation of the values of e_1 , e_2 , and ϵ over the span of the example wing. In general it appears that, for small values of the moment-arm parameter $\frac{e_2 c_r \cos^2 \Lambda}{b'/2} \sqrt{\frac{(EI)_r}{(GJ)_r}}$, the variation of the reversal speed with the sweep parameter $\tan \Lambda \sqrt{\frac{(GJ)_r}{(EI)_r}}$ should be nearly symmetrical and that, for large values of the moment-arm parameter, the reversal speed should tend to be lower for sweptback wings than for sweptforward wings.

The variation of the reversal speed of an unswept wing with the moment-arm ratio is shown in figure 7 (b) for wings which have the same distributions of the parameters e_1/e_1 , and e_2/e_2 , along the span but have different values of e_1 , and

e_2 . The parameter $(\kappa q^*)_{R_0}$ is plotted against the ratio $\frac{1}{1+\epsilon}$, where the value of ϵ is selected at the midaileron station. It is seen that the plot is linear for both the subsonic and supersonic case. The difference in these cases is due to the different variations of e_1 and e_2 along the span; if the variations were the same or if e_1 and e_2 were constant along the span, the two lines of figure 7 (b) would coincide. Since the reversal parameter $(\kappa q^*)_{R_0}$ is proportional to $\frac{1}{1+\epsilon}$ and since the reversal dynamic pressure is directly proportional to the reversal parameter and inversely proportional to the value e_1 , (by definition of the parameter κq^*), it follows that the reversal dynamic pressure is approximately proportional to the ratio $\frac{1}{e_1+e_2}$. From figure 1 it is seen that the sum of e_1 and e_2 represents the distance from the aerodynamic center to the center of pressure of the lift due to aileron deflection and is independent of the location of the elastic axis. This fact corroborates the commonly made observation that the reversal speed is independent of the location of the elastic axis in the case of unswept wings.

The control power and maneuverability cannot be related to the structural and geometric parameters in as relatively simple a manner as the reversal speed. The control power is a function of both the ratio q/q_R and the ratio q_R/q_D ; it normally decreases with q/q_R , the rate of decrease being slow at first and then more rapid for positive values of q_R/q_D (which would generally be obtained for unswept and sweptforward wings) and being rapid at first and then slower for negative values of q_R/q_D (which would generally be obtained for sweptback wings). The variation of the maneuverability should generally be similar to that of the control power since the damping coefficient decreases (or in the case of unswept and sweptforward wings increases) steadily with q/q_D and is independent of q_R/q_D .

From the calculations for the example wings it appears that the control power and maneuverability of sweptback wings tend to be relatively low, particularly at supersonic speeds. A combination of high sweep and large moment arm e_2 may lead to an undesirably low maneuverability. Of course, any increase in the purely aerodynamic effectiveness α_s of the aileron-airfoil combination results in a proportional increase in the lateral-control effectiveness. At supersonic speeds α_s is proportional to the aileron-chord ratio c_a/c , so that an increased aileron chord results in greater maneuverability; at subsonic speeds an increase in the aileron chord is less effective. Another obvious means of raising the reversal speed and of increasing the control power is to increase either the torsional stiffness or the bending stiffness of the structure. In some cases, however, the increase of the reversal parameter $(\kappa q^*)_R$ due to a change in the parameter $\tan A \sqrt{\frac{(GJ)_r}{(EI)_r}}$ (see fig. 7 (a)) produced by a decrease in the torsional stiffness $(GJ)_r$ may

be so rapid as to cause a net increase in the reversal speed.

If the sweep, the moment arm e_2 , the stiffness, and the aileron effectiveness cannot be changed sufficiently to increase the maneuverability, it may be necessary to resort to unconventional control devices. Leading-edge ailerons, for instance, have negative values of the moment arm e_2 , so that wings equipped with them tend to reverse at very high speeds, if at all. This type of configuration has the additional advantage of relatively high effectiveness at transonic speeds. The effectiveness of leading-edge ailerons at subsonic speeds is so low, however, that they would have to be used in conjunction with trailing-edge ailerons to assure satisfactory lateral control at low subsonic speeds; furthermore, they pose some other aerodynamic as well as structural and mechanical problems. Similarly, from an aeroelastic point of view spoilers appear attractive because they tend to have small or negative values of e_2 , but they also pose certain design problems. Consequently, both these devices require careful consideration before they are used to alleviate aeroelastic difficulties in any specific case.

CONCLUDING REMARKS

A method has been presented for calculating the effectiveness and the speed-of reversal of lateral control as well as of the aerodynamic loading and the rolling moment produced by aileron deflection on swept flexible wings of arbitrary stiffness.

It has been shown that the aileron reversal speed decreases with both sweptback and sweptforward wings and that the effectiveness of conventional aileron configurations on sweptback wings at supersonic speeds tends to be relatively low. The control effectiveness and the resulting maneuverability of the airplane may be increased by varying some of the design parameters such as the structural stiffness and, if necessary, resorting to unconventional control devices, such as leading-edge ailerons or spoilers.

REPORT 1025

EXPERIMENTAL AND THEORETICAL STUDIES OF AREA SUCTION FOR THE CONTROL OF THE LAMINAR BOUNDARY LAYER ON AN NACA 64A010 AIRFOIL¹

By ALBERT L. BRASLOW, DALE L. BURROWS, NEAL TETERVIN, and FIORAVANTE VISCONTI

SUMMARY

A low-turbulence wind-tunnel investigation was made of an NACA 64A010 airfoil having a porous surface to determine the reduction in section total-drag coefficient that might be obtained at large Reynolds numbers by the use of suction to produce continuous inflow through the surface of the airfoil (area suction). In addition to the experimental investigation, a related theoretical analysis was made to provide a basis of comparison for the test results.

Full-chord laminar flow was maintained by application of area suction up to a Reynolds number of approximately 20×10^6 . At this Reynolds number, combined wake and suction drags of the order of 38 percent of the drag for a smooth and fair NACA 64A010 airfoil without boundary-layer control were obtained. The minimum experimental values of suction-flow coefficient for full-chord laminar flow were of the same order of magnitude as the theoretical values and decreased with an increase in Reynolds number in the same manner as the theoretical values. It seems likely from the results that attainment of full-chord laminar flow by means of continuous suction through a porous surface will not be precluded by a further increase in Reynolds number provided that the airfoil surfaces are maintained sufficiently smooth and fair and provided that outflow of air through the surface is prevented.

Although area suction was able to overcome the destabilizing effects of an adverse pressure gradient such as that which occurs over the rear portion of an airfoil, area suction does not appear to stabilize the boundary layer completely for relatively large disturbances such as those which might be caused by protuberances that have a height comparable to the boundary-layer thickness.

INTRODUCTION

The stability theory for the incompressible laminar boundary layer is an analysis of the damping or amplification of vanishingly small two-dimensional aerodynamically possible disturbances in the boundary layer (reference 1). A possible definition in the physical sense of a small disturbance is one that does not produce transition from laminar to turbulent flow at its origin in contrast with a large

disturbance, which does cause immediate transition. Small disturbances may either amplify as they progress downstream and eventually grow large enough to cause turbulence or they may be damped and cause no change in the downstream flow; if small disturbances of all frequencies are damped rather than amplified, the laminar boundary layer is considered stable (reference 2).

Theoretical investigations have been made of the characteristics of flows past a flat plate through which there is a small normal velocity and, in addition, the stability theory has been used to calculate the stability of the laminar boundary layer for this type of flow. Examples of some of this theoretical work can be found in references 3 to 7 and in British work (not generally available). The results of these analyses indicate that a small normal velocity into the surface at all points along the surface has a large stabilizing effect on the laminar layer. Inasmuch as there appear to be no data that show this effect experimentally, an investigation of the effect of area suction on the boundary-layer stability is being made in the Langley low-turbulence pressure tunnel. Three suction arrangements were investigated on an NACA 64A010 airfoil that had porous sintered-bronze surfaces. Measurements were made up to a Reynolds number of approximately 20×10^6 and included wake drags, suction-flow quantities, suction losses, and a few boundary-layer velocity profiles.

In order to provide a basis of comparison for the measured suction flows, the stability of the laminar boundary layer was calculated for two important cases of chordwise suction distribution for the test airfoil. Theoretical results are also presented for a flat plate with uniform suction. The calculations were made by combining Schlichting's theory for the computation of the laminar boundary layer (reference 8) with Lin's theory for the determination of the stability of the laminar velocity profile (reference 1). Suction quantities necessary to keep the boundary layer neutrally stable at all points along the airfoil chord were calculated for Reynolds numbers of 6×10^6 , 15×10^6 , and 25×10^6 . The minimum suction quantities required to keep the boundary layer stable were obtained also for the case where the inflow velocity is constant over the entire surface.

Braslow, and Neal Tetervin, 1949, and NACA TN 2112, "Further Experimental Studies of Area Suction for the Control of the Laminar Boundary Layer on a Porous Bronze NACA 64A010 Airfoil" by Albert L. Braslow and Fioravante Visconti, 1950.

SYMBOLS

α_0	section angle of attack
c	airfoil chord
b	span of porous surface
x	distance along chord from leading edge of airfoil
s	distance along surface from leading edge of airfoil
y	distance normal to surface of airfoil
ρ_0	free-stream mass density
U_0	free-stream velocity
q_0	free-stream dynamic pressure $\left(\frac{1}{2} \rho_0 U_0^2\right)$
U	local velocity parallel to surface at outer edge of boundary layer
u	local velocity parallel to surface and inside boundary layer
Q	total quantity rate of flow through both airfoil surfaces
C_Q	suction-flow coefficient $\left(\frac{Q}{bcU_0}\right)$
H_0	free-stream total pressure
H_i	total pressure in model interior
p	local static pressure on airfoil surface
S	airfoil pressure coefficient $\left(\frac{H_0 - p}{q_0}\right)$
R	free-stream Reynolds number based on airfoil chord
C_P	suction-air pressure-loss coefficient $\left(\frac{H_0 - H_i}{q_0}\right)$
c_{d_w}	section wake-drag coefficient
c_{d_s}	section suction-drag coefficient $(C_Q C_P)$
c_{d_T}	section total-drag coefficient $(c_{d_s} + c_{d_w})$
δ^*	displacement thickness $\left(\int_0^\infty \left(1 - \frac{u}{U}\right) dy\right)$
θ	momentum thickness $\left(\int_0^\infty \frac{u}{U} \left(1 - \frac{u}{U}\right) dy\right)$
$R_{\delta^*} = \frac{U \delta^*}{\nu}$	
ν	kinematic viscosity
v_0	velocity through airfoil surface (for suction, $v_0 < 0$; for blowing, $v_0 > 0$)
Δp	static pressure drop across porous surface
c_{v_0}	porosity factor, length ² $\left(\left \frac{v_0}{\Delta p}\right \mu t\right)$
μ	absolute viscosity
t	thickness of porous material
$z = \left(\frac{\theta}{c}\right)^2 \frac{U_0 c}{\nu}$	(reference 8)
G	function of k and k_1 (reference 8)
$k = z \frac{d \frac{U}{U_0}}{d \frac{s}{c}}$	(reference 8)
$k_1 = f_1 \sqrt{z}$	(reference 8)
$f_1 = \frac{-v_0}{U_0} \sqrt{\frac{U_0 c}{\nu}}$	(reference 8)

K	profile shape parameter (reference 8)
$\eta = \frac{y}{\delta_1}$	(reference 8)
δ_1	measure of boundary-layer thickness (reference 8)
u_c	velocity of disturbance in boundary layer
$R_{\delta^* cr}$	value of R_{δ^*} at which disturbance is neither damped nor amplified

MODEL

Photographs of the 3-foot-chord by 3-foot-span model mounted in the Langley low-turbulence pressure tunnel are presented as figure 1. The model was formed to the NACA 64A010 profile, ordinates for which are presented in reference 9. The theoretical pressure distribution of this airfoil at zero angle of attack is presented in figure 2.

A sketch showing the details of the model construction is presented as figure 3. The model was constructed with two hollow cast-aluminum end sections which were machined to contour and connected to an under-contour hollow center casting that served as a base support for the bronze skin. The skin was directly supported on a chordwise arrangement of $\frac{1}{4}$ -inch spanwise rods which were attached to the under-contour casting. The chordwise locations of these rods are

(a) Leading edge.

(b) Trailing edge.

FIGURE 1.—NACA 64A010 airfoil model with porous sintered-bronze surface mounted for area-suction studies in Langley low-turbulence pressure tunnel.

shown as figure 4. This arrangement of support rods, in which the rods made essentially line contact with the skin, was intended to provide as much open area as possible on the inner side of the skin so that very little of the skin would be blanked off from the suction flow. The center casting was perforated with 1-inch holes over the center portion and 1-inch slits at the model leading and trailing edges to provide a passageway for the air from the skin into the inner chamber of the hollow casting. This model configuration is herein referred to as configuration 1.

The model was made such that the chordwise flow could be altered by installing orifices in the model base casting as shown in figure 4. Flow between compartments formed by the $\frac{1}{4}$ -inch rods could be prevented by sealing the rods to

FIGURE 2.—External-pressure and suction-pressure distributions for porous bronze NACA 64A010 airfoil model. $\alpha_0 = 0^\circ$.

the skin with rubber cement. The model arrangement with orifices and compartment seal is referred to herein as configuration 2. A photograph which shows model configuration 2 with the skin removed is shown as figure 5.

For configurations 1 and 2, the upper and lower surfaces of the 13-inch center section of the span were constructed from a continuous sheet of porous sintered bronze with a single spanwise joint at the model trailing edge, which was fastened only at the spanwise edges to $\frac{1}{2}$ -inch inner end plates; consequently, a 12-inch span of the skin was left open to suction. In order to prevent outflow from the upper and lower leading-edge compartments, the leading-edge skin of configuration 2 was saturated with lacquer for a distance of 1 inch ($\frac{s}{c} = 0.028$) from the leading edge on both upper and lower surfaces.

A third suction arrangement was investigated (configuration 3) wherein the orifices in the model base casting were removed and a low-porosity skin was installed. Flow between compartments was not prevented by sealing the rods to the skin. Two bronze sheets were used to form the center part of the airfoil surfaces from the trailing edge to the 2-percent-chord station. A sheet of duralumin was formed around the leading-edge contour and butted to the bronze. The skin was fastened at the butt joint in addition to being fastened along the spanwise edges to the $\frac{1}{2}$ -inch inner end plates; the leading edge was glazed and faired with hard-drying putty up to the 5-percent-chord station.

The same sintered-bronze sheet was used in configurations 1 and 2 and was fabricated of spherical bronze powder that was specified to be small enough to pass through a 200-mesh screen but too large to pass through a 400-mesh screen. The thickness of the sheet was found to vary about ± 0.010 inch from a mean of 0.080 inch. The sintered-bronze sheets of configuration 3 were approximately 0.090-inch thick and

FIGURE 5.—NACA 64A010 airfoil model with porous sintered-bronze surface removed.

were fabricated of spherical bronze powder which was small enough to pass through a 400-mesh screen.

The porosity of the sintered-bronze material was such that the flow quantity varied directly with the pressure drop, as is characteristic of dense filters. With air at standard conditions the measured porosity of the skin of configurations 1 and 2 and the skin of configuration 3 was such that an applied suction of 0.06 and of 1.84 pounds per square inch, respectively, induced a velocity of 0.5 foot per second through the material; these values amount to porosity factors c_{r_0} equal

to 1.44×10^{-10} and 0.0525×10^{-10} square foot which are independent of the material thickness and the viscosity and density of the flow medium provided that the flow through the material is purely viscous. The outer surfaces of the sintered bronze were sanded to reduce local surface irregularities with a resultant decrease in porosity at local points because of a "smearing over" of metal particles. Frequent vacuum cleaning of the surfaces eliminated large changes in the porosity with time because of dust clog.

Photomicrographs of the sanded skin of configurations 1 and 2 are presented as figure 6 to give a visual indication of the porosity. Figure 6(a) is representative of about 80 percent of the sanded surface. Figures 6(b) and 6(c) indicate the amount by which the metal was smeared as a result of excessive sanding on poorly sintered areas. Less sanding was required for the skin used on configuration 3 inasmuch as the original surface texture was much better than that of configurations 1 and 2. Porosity measurements made after sanding, however, indicated that the average porosity for the whole airfoil was not affected appreciably by the sanding operations.

As a result of a low modulus of elasticity of the material and the variations in thickness, the airfoil contour of configurations 1 and 2 as tested was quite wavy. Absolute variations from the true profile were not measured; however,

(a) Representative of approximately 80 percent of total area.

FIGURE 6.—Photomicrographs of sanded sintered-bronze surface as tested.

a relative waviness survey was made at various spanwise stations with a three-point indicating mechanism (fig. 7). An estimate of the degree of waviness of the bronze surface may be obtained by comparing the profiles for the bronze surface with the profiles of the cast-aluminum end sections; the profiles of the end sections varied no more than ± 0.003 inch from the true airfoil profile. No waviness survey was made on model configuration 3; however, the surfaces were somewhat smoother and fairer than the surfaces of configurations 1 and 2.

APPARATUS AND TESTS

The model was tested in the Langley low-turbulence pressure tunnel and was mounted as shown in figure 1. A detailed description of this tunnel is given in reference 10. Flow measurements for the suction air were made by means of an orifice plate in the suction duct. The suction flow was taken through one of the model end plates and was regulated by varying the blower speed and the diameter of the orifice which was used to measure suction flow.

A static-pressure tube was used to measure the suction pressure in the inner compartment of the center casting. Since the velocity was low, the measured static pressure was very nearly equal to the total pressure. These data were used to obtain the total pressure lost by the suction air in passing from the free stream to the inner chamber of the model and were also used to give an indication of outflow which occurred when the pressure inside the model was greater than the lowest pressure on the airfoil surface.

FIGURE 8.—Spanwise variation of section wake-drag coefficient on porous bronze NACA 64A010 airfoil model for three Reynolds numbers and suction-flow coefficients. $\alpha_0 = 0^\circ$; configuration 3.

For configurations 1 and 3, the skin was the only resistance to the suction; that is, air passages between the skin and the inner chamber were large enough to make the internal losses low in comparison with the pressure drop through the skin. The use of flow-control orifices in each compartment of configuration 2 had the disadvantage that any one set of orifices such as shown in figure 4 was able to produce a near-uniform chordwise inflow distribution only at free-stream Reynolds numbers below the design value, which for this case was 6.0×10^6 . No attempt was made to measure the flow in each compartment because of the exploratory nature of the tests. To obtain an indication of outflow through the skin, however, the suction pressure was measured in compartment 5 under the upper-surface skin (fig. 4). Because of the peculiarities of the throttling system, calculations indicated that compartment 5 would be the most critical to outflow.

Spanwise surveys of section wake-drag coefficient over the part of the model covered with the porous skin indicated appreciable variations in wake drag. Examples of these variations are shown in figure 8 for configuration 3. The large variations, occurring only over the outer portions of the bronze skin, were due to disturbances originating at or near the junctures between the bronze skin and the solid model end sections; over a spanwise region of approximately 4 inches at the center of the bronze skin, the measured wake-drag coefficients were rather constant. The wake drags and boundary-layer measurements presented herein were obtained at the center region of the model and are believed to correspond to the true two-dimensional conditions and to be essentially uninfluenced by the flow disturbances outside this region. All wake drags were measured with a survey rake located at about 70 percent of the chord behind the model trailing edge. Boundary-layer measurements were obtained with a conventional multitube "mouse" (reference 11) located on the center line of the upper surface of configuration 1 at 83 percent of the chord. Station 0.83c was the most rearward position at which the mouse could be mounted conveniently. The tests were made for Reynolds numbers up to 19.8×10^6 and for suction-flow coefficients up to 0.01 with the model set at zero angle of attack.

RESULTS AND DISCUSSION

THEORETICAL

In order to provide a standard of comparison for the experimental results, the characteristics of the laminar boundary layer were calculated for flow into the surface of the NACA 64A010 airfoil at an angle of attack of 0° . The minimum suction quantities necessary to keep the laminar boundary layer neutrally stable over the entire surface at Reynolds numbers of 6×10^6 , 15×10^6 , and 25×10^6 were computed. The stability of the boundary layer was also investigated for cases in which the velocity through the surface was everywhere the same.

The boundary-layer velocity profiles and thicknesses were calculated by the Schlichting method (reference 8), an approximate method. The velocity profiles of the Schlichting method are a single-parameter family of curves for which the parameter depends on the velocity of flow into the surface, the pressure gradient along the surface, the boundary-layer thickness, and the kinematic viscosity of the fluid. The single-parameter family of velocity profiles is used with the boundary-layer-momentum equation to obtain a first-order differential equation. In the calculations, the differential equation of reference 8 was integrated by Euler's step-by-step method. In the process of integrating the differential equation, the boundary-layer profiles and boundary-layer thicknesses are found at each point along the wing surface. The lengths of the steps in the integration process were about the same for all the calculations and were so small that halving them made no important difference for the no-suction case and a Reynolds number of 25×10^6 .

In order to begin the calculation, the value of $\frac{dz}{ds}$, the rate of change of a representative boundary-layer-thickness parameter, at $x=0$ (reference 8) was taken as zero. This value of $\frac{dz}{ds}$ was found from the equation

$$\left(\frac{dz}{ds/c} \right)_{\frac{s}{c}=0} = \left[\frac{z \left(\frac{d^2 U/U_0}{ds/c^2} \right) \frac{\partial G}{\partial k} + \frac{df_1}{ds/c} \sqrt{z} \frac{\partial G}{\partial k_1}}{\frac{dU/U_0}{ds/c} \left(1 - \frac{\partial G}{\partial k} \right) - \frac{f_1}{2} \frac{\partial G}{\partial k_1} \frac{1}{\sqrt{z}}} \right]_{\frac{s}{c}=0}$$

which was obtained by applying L'Hospital's Rule to the equation for $\frac{dz}{ds/c}$, equation (30) of reference 8. In order to continue the calculations as far as the trailing edge of the airfoil, it was necessary to modify slightly the Schlichting method by extrapolation of the curves in figures 5 and 6 of reference 8 beyond the value of k for which the Schlichting method breaks down. The recommendation of reference 8 that separation be assumed to exist when k equals -0.0682 was ignored in order to avoid the contradiction that the boundary-layer profile can become more convex and, at the same time, approach separation.

Lin's approximate formula (reference 1) was used to calculate the Reynolds number $R_{\delta^*_{cr}}$ at which any Schlichting velocity profile is neutrally stable. The stability theory as originally derived assumed that the boundary-layer thickness and velocity distribution did not vary with distance along the surface. Pretsch (reference 12), however, showed that the rates of variations in the thickness and velocity distribution which normally occur can have only a second-order effect on the stability. Lin's stability theory may be used, therefore, to calculate the stability of boundary layers in the presence of pressure gradients. When combined with the Schlichting method, Lin's formula becomes

$$R_{\delta^*_{cr}} = \frac{\left[1 - K\left(2 - \frac{6}{\pi}\right)\right] 25 \left(\frac{du/U}{d\eta}\right)_1}{u_c^4}$$

where u_c is equal to the value of u for which

$$-\pi \left(\frac{du/U}{d\eta}\right)_1 \left[3 - \frac{2 \left(\frac{du/U}{d\eta}\right)_1 \eta}{u/U}\right] \frac{u/U \left(\frac{d^2u/U}{d\eta^2}\right)}{\left(\frac{du/U}{d\eta}\right)^3} = 0.58$$

and where the subscript 1 denotes "at surface." The application of Lin's formula to the Schlichting profiles results in the curve of figure 9 which shows the variation of the critical Reynolds number $R_{\delta^*_{cr}}$ with change in the Schlichting velocity-profile shape parameter K . In figure 10 are shown velocity profiles for three values of K .

FIGURE 9.—Theoretical variation of critical boundary-layer Reynolds number with boundary-layer shape parameter.

A special procedure was used to calculate the distribution of the velocity of flow through the surface that was necessary to keep the boundary layer neutrally stable, $R_{\delta^*} = R_{\delta^*_{cr}}$. For these cases, suction was begun at the first station at which the boundary layer would become unstable without suction. The special method depends on the fact that the condition of neutral stability, $R_{\delta^*_{cr}} = R_{\delta^*}$, can be written as

$$R_{\delta^*_{cr}} = \frac{U}{U_0} \sqrt{z} \sqrt{R} \frac{\delta^*}{\theta}$$

or

$$\frac{R_{\delta^*_{cr}}}{\delta^*/\theta} = \phi(K) = \frac{U}{U_0} \sqrt{z} \sqrt{R}$$

where $R_{\delta^*_{cr}}$, $\frac{\delta^*}{\theta}$, and ϕ are functions only of K . The numerical value of the function $\phi(K)$ depends on $\frac{U}{U_0} \sqrt{z} \sqrt{R}$. With a known value of z at the station at which suction begins, K can be found from the value of $\frac{U}{U_0} \sqrt{z} \sqrt{R}$. All the quantities necessary to proceed to the next station by the step-by-step integration process can be calculated once K is determined. The calculation of these quantities provides the value of the local-suction-velocity ratio v_0/U_0 .

In figure 11 are presented the curves of R_{δ^*} and $R_{\delta^*_{cr}}$ as determined from the calculation for the suction flow required to keep the boundary layer neutrally stable at all points on the airfoil at a Reynolds number of 15×10^6 . The calculated

FIGURE 10.—Several boundary-layer profiles for values of shape parameter K as calculated by Schlichting.

FIGURE 11.—Theoretical chordwise variation of boundary-layer Reynolds number on the NACA 64A010 airfoil for $R_{\delta^*} = R_{\delta^*_{cr}}$; $R = 15.0 \times 10^6$; $C_d = 0.000405$; $\alpha = 0^\circ$.

variation of v_0/U_0 over one surface is shown in figure 12. The suction flow required to keep the boundary layer neutrally stable decreases slowly as the region of falling pressure on the airfoil surface is traversed. When the region of rising pressure is entered, the required suction rises rapidly and continues to increase to the trailing edge. The summary of the results of the computations for the minimum suction quantities is presented in figure 13.

In figure 14 are presented curves of $R_{\delta^*_{cr}}$ and R_{δ^*} for cases where v_0/U_0 is the same over the entire surface. The figures illustrate that by a sufficient increase in the value of the suction parameter $\frac{v_0}{U_0} \sqrt{R}$ the position at which the boundary layer first becomes unstable on the NACA 64A010 airfoil

FIGURE 12.—Theoretical chordwise variation of minimum suction velocity ratio required to produce neutral stability at all points along the chord of the NACA 64A010 airfoil. $R=15.0 \times 10^6$; $\alpha_0=0^\circ$; $C_u=0.000405$.

FIGURE 13.—Theoretical variation of free-stream Reynolds number with minimum suction-flow coefficient required to produce full-chord laminar stability.

can be made to jump from the trailing edge to the region near the leading edge. It may be of interest to note from figure 14 (a) that the Reynolds number can be increased considerably and that the suction coefficient can be decreased appreciably without exposing much of the trailing surface to turbulent flow.

The curves of $R_{\delta^*_{cr}}$ and R_{δ^*} can be found at any Reynolds number, when they are known at one Reynolds number and one value of v_0/U_0 , by noting that if $\frac{v_0}{U_0} \sqrt{R}$ does not vary with Reynolds number then the $R_{\delta^*_{cr}}$ curve is independent of Reynolds number and

$$\frac{R_{\delta^*_2}}{R_{\delta^*_1}} = \sqrt{\frac{R_2}{R_1}} \quad (1)$$

Thus, for a given distribution of $\frac{v_0}{U_0} \sqrt{R}$, which results in a fixed distribution of $R_{\delta^*_{cr}}$, the R_{δ^*} curve for the same distribution of $\frac{v_0}{U_0} \sqrt{R}$ but some other R can be found by equation (1).

At some value of R , R_{δ^*} will touch and yet not cross the $R_{\delta^*_{cr}}$ curve at only one point. (See fig. 14.) This

(a) Critical point near trailing edge; $\frac{v_0}{U_0} \sqrt{R}=1.25$.

(b) Critical point near leading edge; $\frac{v_0}{U_0} \sqrt{R}=1.50$.

FIGURE 14.—Theoretical chordwise variation of boundary-layer Reynolds number and critical boundary-layer Reynolds number for the NACA 64A010 airfoil at three free-stream Reynolds numbers for constant chordwise inflow velocity. $\alpha_0=0^\circ$.

procedure results in one point on the curve of figure 13 which shows the variation of R with the minimum C_q required to produce full-chord laminar stability. Other points on the curve of figure 13 may be found by application of the foregoing procedure to other choices of $\frac{v_0}{U_0} \sqrt{R}$ which result in other $R_{s,cr}$ distributions.

Because the first theoretical studies of the effects of suction on boundary-layer stability were made for the flow over a flat plate, it was thought of interest to include the curve for the flat plate in figure 13 wherein it is illustrated that no suction is required to keep the flow stable on a flat plate when the Reynolds number is sufficiently low. This result is in contrast to that for the airfoil which, because of the adverse

pressure gradient over its rear portion, requires suction at all Reynolds numbers to maintain laminar flow to the trailing edge. Figure 13, however, indicates the rather surprising result that in order to keep full-chord laminar flow at large Reynolds numbers the NACA 64A010 airfoil requires smaller values of C_q than are required for a flat plate. This outcome seems reasonable because, near the leading edge where both the flat plate and the airfoil become critical at high Reynolds numbers, the airfoil profits from the existence of a favorable pressure gradient which increases the critical boundary-layer Reynolds number and decreases the actual boundary-layer Reynolds number over that of the flat plate for the same free-stream Reynolds number.

FIGURE 15.—Variation of section drag coefficients with suction-flow coefficient for porous bronze NACA 64A010 airfoil model. $\frac{C_{q0}}{c_l} = 7.2 \times 10^{-3}$; $\alpha = 0^\circ$; configuration 1.

EXPERIMENTAL CONFIGURATION 1

Wake drag.—The variation of section wake-drag coefficient with suction-flow coefficient is shown in figure 15(a) for Reynolds numbers up to 16.7×10^6 for configuration 1. The static pressure in the interior of this model arrangement was everywhere the same.

At a Reynolds number of 3.0×10^6 the section wake-drag coefficient for $C_q > 0.0028$ was constant and equal to about 0.0008. For a Reynolds number of 5.9×10^6 and for $C_q > 0.0050$ the wake-drag coefficient remained practically constant at 0.0005. The wake drag at Reynolds numbers of 9.0×10^6 , 12.0×10^6 , and 16.7×10^6 , however, decreased steadily with increase in C_q but never became less than the lowest drags obtained at a Reynolds number of 5.9×10^6 , even for a suction-flow coefficient as high as 0.010.

The rapid increase of c_{d_w} that occurred with decreasing C_q for values of C_q slightly less than 0.0024 at a Reynolds number of 3.0×10^6 and for values of C_q less than about 0.0048 at a Reynolds number of 5.9×10^6 was caused by a rapid forward shift of the point of transition from laminar to turbulent flow. The curves in figure 16 show that at 83 percent of the chord, at a Reynolds number of 6.0×10^6 , the boundary layer on the upper surface was laminar for a C_q of 0.0048 but was turbulent for only a slightly lower C_q of 0.0046. Other boundary-layer surveys, not presented herein, indicated that, whenever a rapid increase in drag coefficient accompanied a small decrease in flow coefficient, the boundary layer changed rapidly from laminar to turbulent over a large portion of the surface.

Outflow through the surface occurred when the static pressure inside the skin was greater than the minimum static pressure on the outside of the airfoil. The curves of c_{d_w} against C_q are shown in figure 15 (a) as dash lines when outflow occurred locally and as solid lines when inflow occurred over the whole airfoil. At Reynolds numbers of 3.0×10^6 and 5.9×10^6 the values of minimum C_q required to prevent outflow are seen to be very near the value of C_q at which the drag changes rapidly. It seems probable that outflow produced the rapid forward shift of the transition point

FIGURE 16.—Boundary-layer surveys for two values of suction-flow coefficient at station 0.83c on upper surface of porous bronze NACA 64A010 airfoil model. Configuration 1; $R = 6.0 \times 10^6$; $\alpha = 0^\circ$.

at least for Reynolds numbers up to 5.9×10^6 . From the plots of c_{d_w} against C_q the lowest C_q for which no outflow occurred at each Reynolds number is seen to increase with increasing Reynolds number. This increase of the minimum value of C_q with Reynolds number is a result of the linear variation of flow velocity through the sintered bronze with pressure drop across the surface; the minimum C_q for no outflow increases with the free-stream Reynolds number. A more detailed treatment of this subject is presented in appendix A.

Wake-drag measurements for Reynolds numbers of 9.0×10^6 , 12.0×10^6 , and 16.7×10^6 as shown in figure 15 (a) indicated that laminar flow was probably not maintained over the complete chord of the model. The gradual decrease of wake-drag coefficient with increasing flow coefficient may have been caused either by a gradual rearward movement of the transition point with increasing flow coefficient or by a mere reduction in the size of the turbulent boundary layer. The extreme thinness of the boundary layer at these high Reynolds numbers prevented an accurate determination of its shape even near the trailing edge. It should be noted that full-chord laminar flow was not maintained even though the suction pressures were sufficient to prevent outflow. Theoretical calculations for a Reynolds number of 16.7×10^6 for the configuration and inflow distribution tested indicated that the laminar boundary layer should have been very stable.

The basis for a possible explanation of the transition difficulties at the higher Reynolds number is indicated in reference 13. It is shown therein that the presence of a surface projection will cause premature transition of a laminar boundary layer when the Reynolds number based on the height of the projection and the velocity at the top of the projection exceeds a critical value that is dependent on the geometry of the projection.

Although the numerous protuberances on the bronze skin were sanded to very small dimensions, calculations indicated that the relatively large amount of suction near the leading edge of the model so thinned the boundary layer (especially at the higher Reynolds numbers) that even the particles forming the material probably projected completely through the boundary layer. Because of the high velocity at the top of the particles at the high Reynolds numbers, it seems entirely possible that the critical Reynolds number for the roughness was exceeded in spite of its small height, and thus large disturbances were introduced into the boundary-layer flow. The relatively high drag coefficients measured under such conditions of roughness show that the suction-type profile is not stable to sufficiently large disturbances. The relative stability of the suction-type and no-suction-type profiles to finite disturbances is an important problem for future research.

The difficulties associated with obtaining low drag at high values of the Reynolds number are seen from the foregoing discussion to result from nonuniformity of the chordwise inflow distribution (excessive suction near leading edge) and from the surface irregularities of the material. If the Reynolds number is increased by increasing the value of U_0/ν while the size of the model is held constant, the inflow distribution becomes increasingly nonuniform (see equation (A4), appendix A) and the ratio of the size of the roughness

to the boundary-layer thickness increases. Both of these effects are unfavorable for obtaining low drag at high Reynolds numbers. On the other hand, if c_{r0}/t is held constant (no change in the type of material used) and if the Reynolds number is increased by increasing the chord of the model, the inflow distribution will remain unchanged but the ratio of the size of the roughness to the boundary-layer thickness will vary inversely as the square root of the Reynolds number. For this reason, it seems likely that favorable results can be obtained more easily with a large model than with a small one.

Total drag.—The measured pressure-loss coefficient for the suction air was used to calculate the section suction-drag coefficient and the results are shown in figure 15 (b). The suction-drag coefficient based on the model chord was calculated as $C_P \times C_Q$, which is the drag equivalent of the power required to pump the suction air back to free-stream total pressure. (See appendix B.) In this method of calculating suction drag, the over-all pumping efficiency is considered to be equal to that of the main propulsive system.

As may be seen in figure 15 (b), the variation of c_d was assumed to be linear with C_Q for all Reynolds numbers because of the small variation in C_P which averaged about 1.32. Inasmuch as there is no induced drag on a two-dimensional model, the total drag is the sum of the suction and wake drags. As shown in figure 15 (b), the minimum total drag at a Reynolds number of 3.0×10^6 occurred at a C_Q of about 0.0024, which was slightly less than the minimum C_Q required to prevent outflow; the minimum total-drag coefficient of 0.0042 is an inappreciable improvement over 0.0043, the drag coefficient of a solid NACA 64A010 airfoil with a smooth and faired surface at a Reynolds number of 3.0×10^6 (shown in figure 15 (b) as taken from reference 9). The porous model, however, did not have a completely smooth and faired surface, and a test made with the surface sealed resulted in a no-suction-drag coefficient of approximately 0.0052. The value of 0.0052 is probably somewhat low inasmuch as the surface was sealed with external applications of water glass and wax; as a result, the surface texture was unavoidably improved over that for the unsealed condition although the waviness of the surface was probably not affected. The no-suction-drag coefficient, therefore, would probably be somewhat greater than 0.0052 but less than 0.0092, the value for the extreme condition of standard leading-edge roughness on the solid airfoil (reference 9). The minimum total-drag coefficient increased with increasing Reynolds number with the result that, at a Reynolds number only slightly greater than 3.0×10^6 , no decrease in total drag was obtained by suction. A large proportion of the total drag consisted of suction drag because of the excessive amounts of air required at the leading-edge and trailing-edge surfaces of the airfoil in order to prevent outflow at the minimum pressure point.

The total amount of air that needs to be withdrawn in order to prevent outflow can be greatly reduced by applying suction separately to small portions of the airfoil surface. This purpose was accomplished by dividing the underskin region into separate compartments (configuration 2) as described previously in the section entitled "Model."

CONFIGURATION 2

Wake drag.—Wake-drag tests made on the compartmented model (configuration 2) previous to the tests reported herein indicated that the nose should be sealed for about 1 inch back from the leading edge (fig. 4) in order to obtain low drags at reasonable suction coefficients. The character of the flow at the leading edge before the nose was sealed was not clearly established, but early transition probably occurred because of excessive local outflow near the nose where the external-pressure variation over the first compartment was very large. A better understanding of these outflow difficulties may be gained from the discussion on compartmentation in appendix A.

As shown in figure 17 (a), the section wake-drag coefficient for the model with sealed nose and compartments was less than 0.0010 (for Reynolds numbers as high as 7.8×10^6) for suction-flow coefficients that ranged from 0.0015 at a Reynolds number of 3.0×10^6 to about 0.0035 at a Reynolds number of 7.8×10^6 . At a Reynolds number of 9.1×10^6 the wake drag remained greater than 0.0030 even for flow coefficients as high as 0.0040. Failure to obtain lower wake drags was believed to result from the presence of outflow. Although no outflow and low wake drags might have been obtained at higher suction-flow coefficients, the total drag would not have been reduced because of the excessive suction drags that would have resulted from the large suction quantities.

A comparison of figures 15 (a) and 17 (a) indicates that for equal Reynolds numbers the minimum suction-flow coefficients for which low wake drags were obtained for the compartmented model were about one-third of those required for configuration 1. The largest Reynolds number at which low drag occurred was also extended by compartmenting the model. Thus, low wake drags might be obtained at Reynolds numbers higher than 7.8×10^6 and at suction-flow coefficients lower than 0.0035 if the chordwise distribution of suction were further controlled.

Total drag.—Throughout the low-drag range the average total-pressure loss in the suction air for the compartmented model corresponded to an average pressure-loss coefficient of about 1.40. This average loss coefficient was used to compute the suction-drag coefficient that could be expected for an airfoil compartmented in the same manner as the model tested. The sum of the wake and suction drags is shown in figure 17 (b). At Reynolds numbers of 3.0×10^6 and 5.9×10^6 the minimum c_{dT} was about 0.0028. At

higher Reynolds numbers the minimum c_{dT} was larger because of the larger C_q necessary for low wake drags. In spite of the larger C_q at a Reynolds number of 7.8×10^6 , the minimum total-drag coefficient, 0.0048, was only slightly greater than the drag coefficient for the smooth solid-surface model of the same contour (reference 9) and somewhat

less than the drag coefficient for the porous bronze model with the skin entirely sealed to suction.

The over-all gain in compartmenting the model may be seen by comparing the total drags in figures 15 (b) and 17 (b) from which it is seen that at a Reynolds number of 5.9×10^6 the total drag of the compartmented model (configuration 2)

FIGURE 17.—Variation of section drag coefficients with suction-flow coefficient for porous bronze NACA 64A010 airfoil model. $\frac{c_{r0}}{c_l} = 7.2 \times 10^{-4}$; $\alpha_0 = 0^\circ$; configuration 2.

was only 40 percent of that for the uncompartmented model (configuration 1). In an attempt to improve further the chordwise inflow distribution and thus to obtain full-chord laminar flow and reductions in total drag at larger values of the Reynolds number, the model was equipped with a porous sintered-bronze surface of much lower porosity (configuration 3) as described previously in the section entitled "Model."

CONFIGURATION 3

Wake drag.—The leading edge of this model configuration was sealed to the 5-percent-chord station, which is approximately the chordwise station ahead of which no suction is required theoretically to maintain the boundary-layer

Reynolds number less than the critical value for all test Reynolds numbers anticipated (figs. 11 and 14). The section wake-drag coefficients are plotted against suction-flow coefficient in figure 18 (a) for Reynolds numbers from 5.9×10^6 to 19.8×10^6 . The static pressure in the interior of this model arrangement was everywhere the same as it was for the case of configuration 1.

The variation of drag coefficient with suction-flow coefficient C_q is similar for all Reynolds numbers investigated; that is, an abrupt decrease in drag coefficient to a value of about 0.0008 occurs at some critical value of C_q dependent upon the Reynolds number and is followed by a much more gradual decrease with an increase in C_q . Full-chord

FIGURE 18.—Variation of section drag coefficients with suction-flow coefficient for porous bronze NACA 64A010 airfoil model. $\frac{C_q}{c_l} = 2.33 \times 10^{-10}$; $\alpha_0 = 0^\circ$; configuration 3.

laminar flow is indicated for all values of wake-drag coefficient of about 0.0008 or less, inasmuch as boundary-layer profiles measured during tests of configuration 1 indicated that the boundary layer changed rapidly from turbulent over a large portion of the airfoil to laminar over virtually the full chord whenever a large decrease in drag accompanied a small increase in flow coefficient. The gradual reduction in drag with a further increase in C_Q above the value at which the large drag change occurs corresponds only to a progressive thinning of the full-chord laminar boundary layer. For the tests of configurations 1 and 2, the sudden forward movement in point of transition from laminar to turbulent flow with a small decrease in C_Q was caused by outflow of air through the surface when the static pressure inside the skin was greater than the minimum static pressure on the outside of the airfoil. For the tests of configuration 3, however, the skin was dense enough so that no outflow of air occurred for all values of C_Q investigated at Reynolds numbers up to at least 15×10^6 .

The probable cause of the rapid increase in drag and corresponding forward movement of transition observed in the tests of configuration 3 at Reynolds numbers up to 15×10^6 is revealed by a comparison of the values of C_Q at which the rapid drag rises occurred (fig. 18 (a)) with the minimum theoretical values of C_Q required to keep the laminar boundary layer stable. The experimental values of C_Q at which the rapid drag rises occurred for configuration 3 are plotted in figure 13 for ease of comparison. The minimum experimental values of C_Q for full-chord laminar flow are of the same order of magnitude as the theoretical values and decrease with an increase in Reynolds number in the same manner as the theoretical up to a Reynolds number of 15×10^6 . No outflow of air is known to have existed up to a Reynolds number of 15×10^6 and because of the sealed nose which prevented excessive suction at the leading edge and the especially smooth surface of this model configuration, it is believed that roughness did not cause transition at the low values of C_Q ; therefore, the sudden drag rise probably occurred when the suction became insufficient (at least over a portion of the airfoil chord) to stabilize the laminar boundary layer. At a Reynolds number of 19.8×10^6 outflow of air rather than insufficient suction is likely to have caused the rapid drag rise with a decrease in C_Q . For the porous bronze skin used in the tests of configuration 3, a value of C_P equal to 1.32 was measured at a value of C_Q of about 0.0007 at a Reynolds number of 19.8×10^6 . The minimum local pressure on the airfoil exterior when mounted in the wind tunnel corresponds to a value of pressure coefficient S equal to about 1.31. Inasmuch as C_P decreases with a decrease in C_Q , a value of C_Q slightly lower than 0.0007 would result in outflow of air through the surface and forward movement in transition from laminar to turbulent flow.

The maximum Reynolds number at which recorded data were obtained was 19.8×10^6 . During the tests, however, at a value of C_Q less than 0.001, full-chord laminar flow was maintained up to a Reynolds number of about 24×10^6 as evidenced by a visual observation of the drag manometer which indicated values of the drag coefficient of about 0.0006. Unfortunately, however, a sudden change in the model occurred before any data could be recorded. It was

found that the bronze skin had buckled to such an extent that it was impossible to repeat the full-chord laminar-flow tests at Reynolds numbers somewhat lower than 20×10^6 , although before the skin took the permanent set, repetition of the low-drag results could be made.

Total drag.—The dashed curve of figure 18 (b) represents the variation of c_{d_r} with C_Q for an assumed constant value of C_P equal to 1.32. This value of C_P was chosen in order to present an indication of the minimum suction-drag coefficient required to maintain full-chord laminar flow at any value of the suction-flow coefficient and Reynolds number. As pointed out in the previous section entitled "Wake drag" a value of C_P slightly lower than 1.32 would result in outflow of air through the surface near the 0.40c position and a forward movement in the position of transition. The curves of section total-drag coefficient plotted against C_Q (fig. 18 (b)) are the sums of the suction and wake drags. The minimum section total-drag coefficient decreased with an increase in Reynolds number because of the decrease in C_Q required to obtain low wake drags. At a Reynolds number of 19.8×10^6 the minimum c_{d_r} was 0.0017 as compared with a value of about 0.0045 (estimated from data of reference 14) for an NACA 64A010 airfoil without boundary-layer control at a Reynolds number of 20×10^6 .

COMPARISON BETWEEN THEORY AND EXPERIMENT

The theoretical variations of R_{s^*} , $R_{s^{*cr}}$, and v_0/U_0 with s/c cannot be compared with experiment because local inflow velocities and boundary-layer velocity profiles were not measured. The theoretical total-suction quantities can, however, be compared with the total-suction quantities at the knees of the curves of wake-drag coefficient against suction-flow coefficient.

The following table contains the results of the comparison between theory and experiment:

R	Minimum values of C_Q for laminar stability				
	Theoretical		Experimental		
	Neutral stability	Constant inflow	Configuration 1	Configuration 2	Configuration 3
3.0×10^6	-----	0.00132	0.0028	0.0015	-----
5.9	0.00056	.00096	.0048	.0015	0.00096
7.6	.00051	.00084	-----	.0024	-----
7.8	.00051	.00083	-----	.0034	-----
9.0	.00048	.00077	.0100	-----	-----
12.0	.00044	.00067	-----	-----	.00087
15.0	.00041	.00060	-----	-----	.00063
19.8	.00037	.00054	-----	-----	.00064

Although the chordwise inflow distribution for configuration 3 was more uniform than for either of the previous configurations and although the minimum experimental values of C_Q for laminar stability agree very closely with the theoretical values of C_Q for a constant chordwise inflow, the close agreement cannot be construed as a quantitative check of the theory inasmuch as it is known that the experimental chordwise inflow distribution was not constant.

As shown in the table the minimum experimental values of C_Q for low wake drags for configurations 1 and 2 were appreciably greater than the theoretical values and also increased with an increase in free-stream Reynolds number in contrast to the trend indicated by the theory. This experimental

variation of minimum C_q with Reynolds number for configurations 1 and 2 was shown previously to be a result of outflow of air through the surface and the fact that the minimum C_q for incipient outflow increases with the Reynolds number. (See appendix A.) When it became possible to attain lower values of C_q for incipient outflow at a given Reynolds number by means of the dense skin of configuration 3, the minimum values of C_q became of the same order of magnitude as the theoretical values and had the same trend with Reynolds number as predicted by theory; that is, the minimum C_q decreased with an increase in Reynolds number up to the maximum test Reynolds number at which outflow of air once again prevented a further decrease in C_q for full-chord laminar flow. It appears, therefore, that the theoretical concepts with regard to area suction are valid; the Reynolds number itself, then, should not be a limiting parameter in attainment of full-chord laminar flow provided that the airfoil surfaces are kept sufficiently smooth and fair and provided that outflow of air through the surface is prevented.

Quantitative information on the effects of surface roughness or fairness on the stability of the laminar boundary layer, however, is not yet available although some indications of adverse effects of roughness on the ability to maintain full-chord laminar flow were discussed previously. Another indication of the adverse effects of surface roughness was obtained during a preliminary test run on configuration 1 before the model surfaces were sanded.

For this condition, numerous protuberances existed of sufficient magnitude to cause premature transition of the boundary layer at a Reynolds number as low as 3.0×10^6 . It is possible, however, that the excessive suction at and near the model leading edge may have unduly decreased the boundary-layer thickness relative to the size of the projections; thus, the sensitivity of the boundary layer to the existing disturbances was unnecessarily increased. This explanation, as discussed previously, was prompted by the work of reference 13. Although surface roughness did not appear to cause transition on the sealed-nose configurations (configurations 2 and 3) for the combinations of Reynolds numbers

and flow rates that were tested, it is believed that with other combinations of Reynolds numbers and suction rates (at least for the same model) the boundary layer could become thin enough to allow the surface roughness to cause transition. More information on the effects of area suction on the stability of the laminar boundary layer in the presence of surface disturbances is still required before it can be determined whether area suction can be made practical for the control of the laminar boundary layer.

CONCLUDING REMARKS

Results were presented of a low-turbulence wind-tunnel investigation of an NACA 64A010 airfoil with porous surfaces of sintered bronze. Full-chord laminar flow was maintained by the application of area suction up to a Reynolds number of 19.8×10^6 . At a Reynolds number of 19.8×10^6 , the total-drag coefficient (wake drag plus the drag equivalent of the suction power required) was equal to 0.0017 as compared with an estimated value of 0.0045 for a smooth and fair NACA 64A010 airfoil without boundary-layer control at a Reynolds number of 20×10^6 . The minimum experimental values of suction-flow coefficient for full-chord laminar flow were of the same order of magnitude as the theoretical values and decreased with an increase in Reynolds number in the same manner as the theoretical values. It seems likely from the results that attainment of full-chord laminar flow by means of continuous suction through a porous surface will not be precluded by a further increase in Reynolds number provided that the airfoil surfaces are maintained sufficiently smooth and fair and provided that outflow of air through the surface is prevented. Further research is required, however, to determine quantitatively the effect of finite disturbances on the stability of suction-type velocity profiles.

APPENDIX A

SINTERED-BRONZE SUCTION REQUIREMENTS FOR THE CASE OF INCIPIENT LOCAL OUTFLOW

Several important conclusions may be drawn from a study of the conditions that cause local outflow through a porous sintered-bronze sheet installed on an airfoil as a boundary-layer suction surface. Outflow occurs through any point on the skin where the local static pressure on the inside of the skin is greater than the local external static pressure despite the existence of a difference in pressures at all other points such as to produce inflow. An internal pressure just low enough to prevent outflow at some critical point produces an average value of area suction-flow coefficient which depends on the porosity characteristics of the material.

For a given type of sintered bronze, the velocity into the surface varies directly as the pressure drop across the surface and inversely as the thickness of the sheet and the absolute viscosity of the fluid; thus,

$$v_0 = -\frac{c_{v_0} \Delta p}{\mu t} \quad (A1)$$

A dimensional analysis will show that the factor c_{v_0} has the dimensions of length². This length is related to the effective diameter of the passages leading through the material. So long as the flow is of the purely viscous type, the value of c_{v_0} for a specific piece of porous material may be expected to be independent of the physical characteristics of the fluid passing through the material—that is, the viscosity and density.

Inasmuch as the suction-drag coefficient increases directly as the suction-flow coefficient C_Q (see appendix B), it is of interest to note the manner in which the porosity relation, equation (A1), affects the minimum C_Q necessary to prevent outflow. The average area suction-flow coefficient for both sides of a two-dimensional airfoil may be written as

$$C_Q = \frac{Q}{U_0 c b} = \frac{-\oint b v_0 ds}{U_0 c b} \quad (A2)$$

where the quantity of suction air is obtained by integrating the inflow velocity v_0 over both upper and lower surfaces as indicated by the line integral sign. The inflow velocity given by equation (A1) may be rewritten as

$$v_0 = -\left(\frac{c_{v_0} q_0}{\mu t}\right) \left[\left(\frac{H_0 - H_i}{q_0}\right) - \left(\frac{H_0 - p}{q_0}\right) \right] \quad (A3)$$

where H_i is equal to the internal static pressure because the internal velocity, and therefore the dynamic pressure, is extremely low. The two relations in equation (A3), $\frac{H_0 - H_i}{q_0}$ and $\frac{H_0 - p}{q_0}$, are the suction pressure-loss coefficient and the external airfoil pressure coefficient, respectively. The inflow velocity at any point is now

$$v_0 = -\frac{c_{v_0} q_0}{\mu t} (C_P - S)$$

or

$$\frac{v_0}{U_0} = -\frac{c_{v_0}}{2ct} R (C_P - S) \quad (A4)$$

The suction-flow coefficient for the whole wing can now be written as

$$C_Q = -\frac{c_{v_0} R}{2ct} \oint (C_P - S) d\frac{s}{c} \quad (A5)$$

It may be seen by equation (A5) that, if conditions of airfoil pressure coefficient and suction pressure-loss coefficient remain fixed for a given porous-skin model wherein c_{v_0} , t , and c are fixed, the value of C_Q to be associated with a given value of $\oint (C_P - S) d\frac{s}{c}$ will vary linearly with R . Thus, for the outflow value of the integral where C_P equals S at some point on the airfoil and is higher at all other points, the value of C_Q corresponding to outflow will increase linearly with increasing R , a result approximately in agreement with experimental results.

In order to have like test conditions for like Reynolds number as ρ , U_0 , c , and μ are varied, it is necessary that c_{v_0}/t vary directly with c . When models of different chords are geometrically similar to the extent that t is proportional to c , then c_{v_0} must vary directly as c^2 . This result would be expected since it means that the effective diameter of the passage must vary directly as the chord; that is, the geometrical similarity must include the detailed geometry of the structure of the porous material, as well as the over-all dimensions of the model.

For like airfoils of different chords covered with the same porous material, equation (A4) indicates that the inflow

distribution at any chordwise position is unchanged if R is proportional to c —that is, if U_0/ν is a constant. Thus, if the same airfoil profile were used throughout the span of a tapered wing and the wing were entirely covered with the same porous material, the inflow distribution would be similar for all sections of the tapered wing for the convenient condition of a constant suction pressure within the wing.

Compartmentation of an area-suction model can be used as a method for improving the chordwise inflow distribution so that excessive suction flows will not occur at any point, but, if this method is used, each compartment must be considered as a source of outflow. The flow removed through each compartment can be decreased by decreasing the pressure drop across the porous surface with a throttling device; and thus the effective C_p based on the static pressure in the compartment becomes less for no outflow than the C_p that would be required at the point of maximum S on the airfoil. (See fig. 2.) The net result of compartmenting the whole airfoil is

that for no outflow the sum of the incremental values of C_q for each compartment will be less than the minimum C_q required for no outflow for the uncompartmented model; furthermore, the greater the number of compartments, the greater is the decrease in the value of total C_q for incipient outflow. The end point of more and more compartments is that the chordwise inflow distribution can be set to any value desired. The greatest difficulty in compartmenting is experienced at and near the nose where even very small compartments must combat a very high chordwise change in pressure drop and thus of inflow distribution because of large variations in the external pressure. Inasmuch as extreme compartmentation may result in an immense construction problem, it may be more desirable to provide a skin which has a chordwise variation of porosity that will produce the desired inflow distribution. Such a skin could be obtained by a chordwise variation of either the thickness or the density of the material.

APPENDIX B

DETERMINATION OF SUCTION-DRAG COEFFICIENT

If it is assumed that the suction air is pumped back to free-stream total pressure by a blower and duct system which together have an efficiency of η_s , then the power required may be written as

$$P = \frac{Q(H_0 - H_t)}{\eta_s}$$

where H_t is the average total pressure of the suction as measured at a point under the surface of the wing and H_0 is the free-stream total pressure.

If the flow quantity is expressed as the suction-flow coefficient

$$C_Q = \frac{Q}{U_0 bc}$$

and the total pressure defect is expressed as a pressure-loss coefficient

$$C_P = \frac{H_0 - H_t}{q_0}$$

then the power may be written as

$$P = \frac{C_Q U_0 bc C_P q_0}{\eta_s} \quad (B1)$$

If this amount of power were to be supplied by the airplane propulsive system of efficiency η_p , then the equivalent drag to be associated with this power could be written as

$$D = \frac{P \eta_p}{U_0}$$

or

$$c_{d_s} bc q_0 = \frac{P \eta_p}{U_0} \quad (B2)$$

where the equivalent drag is expressed in terms of a suction-drag coefficient based on the area of the wing.

Equations (B1) and (B2) permit the suction-drag coefficient to be expressed as

$$c_{d_s} = C_Q C_P \frac{\eta_p}{\eta_s}$$

On the condition that the blower system operates as efficiently as the propulsive system, the suction-drag coefficient reduces to

$$c_{d_s} = C_Q C_P \quad (B3)$$

REPORT 1926

NACA INVESTIGATION OF FUEL PERFORMANCE IN PISTON-TYPE ENGINES

By HENRY C. BARNETT

PREFACE

It is generally recognized that the piston-type engine will continue to play an important role in air transportation for an indefinite period in spite of the intensive effort now being devoted to gas-turbine power plants. For this reason, past researches conducted in piston engines are still of interest in the solution of current problems relating to such engines. In order to simplify the task of using the data from previous investigations, an effort has been made to compile a portion of these data into a single reference source.

This particular report is a compilation of many of the pertinent research data acquired by the National Advisory Committee for Aeronautics on fuel performance in piston engines. The original data for this compilation are contained in many separate NACA reports which have in the present report been assembled in logical chapters that summarize the main conclusions of the various investigations. Complete details of each investigation are not included in this summary; however, such details may be found, in the original reports cited at the end of each chapter.

REPORT 1026

CHAPTER I

HIGH-SPEED PHOTOGRAPHIC STUDIES OF KNOCKING COMBUSTION

By C. DAVID MILLER*

At the Summer Meeting of the Society of Automotive Engineers in 1946, Mr. C. David Miller of the NACA presented a paper entitled "Roles of Detonation Waves and Autoignition in Spark-Ignition Engine Knock as Shown by Photographs Taken at 40,000 and 200,000 Frames per Second." This paper was a summary of the NACA high-speed photographic studies of combustion in engine cylinders and it is reproduced substantially in its original form as chapter I of this report. The same material, under the title given above, was previously published in the Transactions of the Society of Automotive Engineers in January, 1947.

The National Advisory Committee for Aeronautics has been using high-speed motion-picture photography in research over a period of more than 20 years and has applied this method to the study of combustion within engine cylinders since 1933. By the early part of 1936 it had become apparent that commercially available cameras were not fast enough for the study of engine combustion, particularly for the study of spark-ignition engine knock. For this reason work was begun at Langley Field early in 1936 on the development of a high-speed camera using a newly invented optical system (reference 1). This camera, which was fully described in reference 2, will be referred to throughout this paper as the high-speed camera. It was operated successfully at 40,000 photographs (or frames) per second on its first test late in 1938 and has been used since that time principally in the study of knock in the spark-ignition engine at Langley Field, Va., and at Cleveland, Ohio. It was soon found, however, that even 40,000 frames per second was inadequate for the study of spark-ignition engine knock, and work was begun in 1939 at Langley Field on the development of a still faster camera. This development was based on another optical system (invented early in 1939) entirely unlike that of the high-speed camera developed in the years 1936 to 1938. (See reference 3.) Construction of a camera incorporating the new optical system was completed in 1941. This camera will be referred to throughout this paper as the ultra-high-speed camera. The ultra-high-speed camera could not be operated satisfactorily according to the original design. The difficulties were not directly associated with the optical system of the camera but with incidental mechanical details. Development of the design, continued since 1941, has not yet been completed. One

photograph of the phenomenon of spark-ignition engine knock, however, was secured with the ultra-high-speed camera at Cleveland at the rate of 200,000 frames per second. It is believed that pictures can eventually be obtained with this camera at a speed several times greater than 200,000 frames per second.

Results of the research work done with the high-speed camera and the ultra-high-speed camera have been reported on a restricted basis during the war years except for one paper (reference 4) presenting a small amount of work on diesel combustion. A report on spark-ignition engine combustion printed in 1941 (reference 5) presented preliminary results and showed that the knock reaction occurred in less than 50 microseconds, and that this reaction may be preceded by much slower exothermic end-gas reactions. Reference 6 printed in 1942 included additional preliminary results and included indications that the knock reaction may sometimes originate at a point outside of the end gas and that the knock reaction may be preceded by mild vibrations which become manyfold intensified at the instant of knock. In references 5 and 6, the characteristic reaction occupying less than 50 microseconds as seen in the photographs was more or less assumed to be the knock reaction on the basis of the general appearance of the motion pictures. In reference 7, issued in 1943, this characteristic reaction was definitely shown to begin simultaneously, within 25 microseconds, with the onset of violent knocking gas vibrations as shown by a piezoelectric pressure pickup exposed to the end gas in the combustion chamber. Reference 7 included additional indications that the knock reaction does not necessarily originate in the end gas. Reports released in 1944 showed that the knock reaction instantly rendered a large part of the unreleased energy of combustion chemically unavailable (reference 8), revealed several definite facts about the previously noted preknock vibrations, and showed the development of several types of preknock end-gas autoignition as well as autoignition in a large end-gas volume practically without any resultant knock (reference 9). In 1946 a report was released presenting analyses of some of the high-speed pictures indicating knocking detonation-wave velocities ranging from one to two times the speed of sound in the burned gases (reference 10), and ultra-high-speed photographs taken at 200,000 frames per second have been released confirming the detonation-wave character of knock with a wave speed of 6800 feet per second (reference 11).

*Now with Battelle Memorial Institute.

It is the purpose of the present paper to offer a unified report of the facts concerning spark-ignition engine knock that have been previously reported on a restricted basis and to include as an introduction to the unified report the results of a literature study which the author believes support the new concept of knock that he and his coworkers have obtained from the high-speed pictures. A synopsis of the unified report has also been prepared in the form of a motion-picture film (reference 12). For a general history of the application of photographic methods to engine combustion, see references 4, 10, and 11.

Knock, one of the most serious limitations on the performance of the present-day reciprocating aircraft engine, has been plaguing the designers and users of spark-ignition engines in general at least since 1880, when Clerk suppressed extremely violent knock by the use of water (references 13 and 14). Knock has been the subject of intensive research by groups in various countries for about 25 years.

The past researches on knock have uncovered an immense amount of information, not only concerning the basic nature of knock but also concerning the question of what to do about it. The information available on the basic nature of knock has led most writers, at least in the United States, to accept the autoignition theory in preference to all others. (Though many writers refer to knock as "detonation," they do not mean to imply that they believe knock is caused by a detonation wave.) Only a few dissenters (references 14 to 19) have questioned the adequacy of the autoignition theory.* The photographs obtained with the high-speed camera and the ultra-high-speed camera have forced the author and his coworkers to join the ranks of the dissenters.

The available information on what should be done about knock is outside the scope of this paper and is so well known that it needs no review here. The available information is undoubtedly accurate as far as it goes and is so extensive that many practical workers with engines and fuels even discount the need for definite knowledge as to what knock is.

Aside from the fact that any kind of knowledge concerning any process of nature rarely proves in the end to be of no practical value, some urgent reasons exist for determining exactly what knock is. Probably the most important reason is associated with the fact that little is definitely known even about the harmfulness of knock. As will be shown in this paper, there are probably more than one and perhaps even more than two phenomena that are regarded as knock when they occur in the combustion chamber. In view of the possibility that these phenomena may not all be harmful, it seems urgently desirable to learn which are harmful and how to distinguish between one of the phenomena and another. As was pointed out by Boerlage in 1937 (reference 19), the noise of knock cannot be regarded too seriously until the harm done has been demonstrated to be proportional to the noise. In order to distinguish between the forms of knock and to know which are harmful and which are not, the logical first step appears to be that of learning what the phenomena are and under what conditions the various phenomena occur.

Other reasons for seeking the true explanation of knock are the possible saving of much labor involved in developing and testing ideas based on a possibly false conception of the nature of knock, acquisition of additional fundamental knowledge concerning chemical laws that might prove useful in other fields, and the possibility, however remote, that some new and simpler solution to the knock problem might be suggested.

Next to autoignition, the detonation-wave theory probably is generally regarded as the most plausible of the many theories that have been advanced to explain knock. Study of the photographs taken at 40,000 frames per second over a period of 6 years has convinced the author that a detonation wave, or some phenomenon very much like a detonation wave, actually is involved in the type of knock most frequently encountered in the modern aircraft engine. Autoignition also appears to be often involved in knock. A combined autoignition and detonation-wave theory has been proposed (reference 10) on the basis of a study of the high-speed photographs and the available literature concerning knock.

The autoignition and detonation-wave theories of knock are actually in agreement in many respects. According to either theory knock occurs only after the flame has traveled from the spark plug through most of the fuel-air mixture at speeds ranging from below 50 feet per second to several hundred feet per second, depending on engine speed, fuel-air ratio, and a number of other variables. This speed of 50 to several hundred feet per second is a low speed from the standpoint of tendency to produce shock; it is the normal rate of burning in nonknocking operation. Again according to either theory, the shock known as knock is produced by the sudden inflammation of the end gas, the gas that has not yet been ignited at the time knock occurs by the normal travel of the flame from the spark plug.

If the end gas is considered as being divided into a very large number of extremely small cells or increments, it is clear that no great shock will result from the burning of the individual increments at widely different times, however fast the burning of each increment may be, and it is also clear that shock will not result from the simultaneous burning of all the increments unless each increment goes through the burning process within an extremely small time interval. Shock will result, according to either theory, only if each increment burns within a very small time interval and all increments burn at the same time within a very small limit. If these two conditions are satisfied, then the end gas does not have time to expand during the burning of the increments and a very high pressure is produced in the end gas relative to the gas in the other parts of the chamber. The subsequent expansion of the end gas sets up a violent vibration or system of standing waves throughout the entire contents of the combustion chamber. Such a system of standing waves was shown to be the cause of audible knock, at least under certain conditions, by the researches reported by investigators at the Massachusetts Institute of Technology and at General

*Since the presentation of this paper in June 1946, prior opposition to the autoignition theory by several others has come to the author's attention.

Motors between 1933 and 1939 (references 20 to 23). Slow-motion pictures of these vibrations taken at 40,000 frames per second were first presented at an SAE meeting in March 1940 (reference 23).

The only point of difference between the autoignition and detonation-wave theories is in the means of synchronizing the ignition of the end-gas increments, that is, the mechanism that causes all end-gas increments to burn at the same time within a small enough limit to cause shock.

The argument presenting the synchronizing mechanism of the autoignition theory is as follows: Each end-gas increment will burn explosively when it attains some certain combination of temperature and density (or the equivalent of some particular temperature-density history, as suggested by Leary and Taylor of M. I. T. in reference 24). All end-gas increments are adiabatically compressed at the same time and at the same rate by the expansion of the burning gas behind the flame front. All increments of end gas should, therefore, reach the critical combination of temperature and density at which they will explode at the same time.

In an analysis of the synchronizing mechanism of the autoignition theory, it should be considered that the compression of the end gas by the burning gases is accomplished by an infinite series of sound waves. A given condition of temperature and density should, therefore, be expected to travel through the end gas from the burning zone at the speed of sound. The combination of temperature and density in any end-gas increment may be expressed as some function F , so defined that each end-gas increment will explode when $F = F_{cr} \pm \delta$, the term δ representing an element of uncertainty due to random variation in the behavior of the end-gas increments or to random inhomogeneities. The value of F in each end-gas increment will increase by an amount equal to 2δ in some time interval τ . Now if τ is not greater than the order of the time interval τ' required for a sound wave to pass through the unignited end gas, then it should be expected that autoignition would take place as an explosive reaction traveling through the unignited end gas at least at the speed of sound. It would not take place as a simultaneous reaction throughout the end gas. The explosive reaction would constitute some kind of explosive wave, if not an actual detonation wave. This wave might travel too slowly to produce shock and to be regarded as a true detonation wave. Obviously, however, the less shock the wave produced the less the knocking sound heard outside the engine.

If τ is assumed to be much greater than the order of τ' , then autoignition should be expected to develop homogeneously throughout the end zone. The pressure built up by the combustion of the end gas, however, is relieved also by an infinite series of sound waves. Consequently, if τ is many times greater than the order of a time interval τ'' required for a sound wave to pass through the *autoigniting* end gas, the pressure in the end gas would be relieved many times during the process of autoignition and shock would not occur.

The magnitude of the time interval τ apparently must

lie within a range somewhat greater than τ' but not many times greater than τ'' if knock is to be caused by a homogeneous autoignition of the end gas. Above this range of values for τ no shock can occur; below this range of values the autoignition must occur as something similar to a detonation wave, and becoming more and more like a detonation wave as the knock intensity increases. (Knocks of different intensity can occur with the same end-zone volume according to unpublished NACA photographic records.) The time interval τ'' is a variable for different stages of the homogeneous autoignition process and reaches a value much less than τ' during the later stages of the process. The range of values of τ greater than τ' but not many times greater than τ'' must, therefore, be quite narrow.

Autoignition, either as a detonation wave or as a homogeneous reaction with τ slightly greater than τ' , seems a very plausible synchronizing mechanism. Before it is accepted conclusively, however, the available evidence should be carefully studied as to whether it actually is an adequate synchronizing mechanism. The evidence should also be investigated as to whether autoignition of the individual gas increments proceeds to completion within a short enough time interval to produce shock. A considerable amount of evidence exists against autoignition as the sole cause of the standing waves of knock on both counts, as will be shown in the later parts of this paper.

The synchronizing mechanism postulated by the detonation-wave theory is an intense compressive shock wave that travels through the end gas at supersonic velocity. Each gas increment is ignited probably by the combination of the sudden intense compression occurring in the shock front, the action of chain carriers in the shock front, and the radiation of heat from the shock front. The entire combustion, or some definite stage of the combustion, of each gas increment is presumed to occur in the shock front and to release a large amount of energy immediately behind the shock front. The energy released by the gas increments immediately behind the shock front maintains the high pressure required to propagate the shock front through the charge. Such a phenomenon, being an intense shock wave, would obviously set up vibration of the gases throughout the combustion chamber. If, as the author holds, simple homogeneous autoignition can no longer be accepted as the sole cause of the knocking gas vibrations, the detonation wave appears to be the only remaining plausible explanation that has been suggested. The detonation wave, however, may be only the end result of a comparatively slow homogeneous end-gas autoignition or the detonation wave may act as the initiator of a very rapid homogeneous combustion which in its turn sets up the violent gas vibrations.

A literature-based argument in favor of a combined detonation-wave and autoignition theory of knock will be found in the first part of the section called "Discussion and Analysis," and the unified report of the findings obtained from the high-speed and ultra-high-speed photographs will be found in the second part of the same section.

DEFINITION OF TERMS

Throughout the present paper the following terms are used with the meanings indicated:

1. Knock: Any type of reaction occurring within combustion-chamber contents and producing objectionable noise outside the engine, but not including the phenomenon of early combustion caused by too early spark timing or by early ignition from a hot spot.

2. Explosive knock reaction: A specific reaction observed in NACA photographs of knocking combustion taken at 40,000 frames per second, usually appearing instantaneous when the photographs are projected at the normal rate of 16 frames per second and coinciding chronologically with the onset of gas vibrations as seen in the photographs. (This reaction, being regarded as one form of knock, will sometimes be referred to simply as "knock" when the context makes the meaning clear.)

3. Flame front: The continuously changing surface that separates unflamed parts of the cylinder charge from the burning parts of the charge that have been ignited by the advance of the flame from the spark plug.

4. Autoignition: Spontaneous burning in any part of the cylinder charge not caused by a spark, by contact with a flame front, or by contact with a hot spot, and including not only the initiation of burning but the entire process of burning resulting from the spontaneous ignition.

5. Shock wave: An intense compressive wave traveling through gas at supersonic velocity, the front of such wave constituting an abrupt increase or practical discontinuity in temperature, density, and velocity of the gas.

6. Detonation wave: A type of wave often observed in long tubes consisting of a shock wave traveling through a gas or a gas mixture and causing a reaction of the gas in the shock front, such reaction releasing energy immediately behind the shock front, the energy so released serving to maintain the pressure needed behind the shock front to propagate the wave.

DISCUSSION AND ANALYSIS: LITERATURE-BASED ARGUMENT FOR COMBINED DETONATION-WAVE AND AUTOIGNITION THEORY OF KNOCK

Autoignition theory.—The autoignition theory of knock was suggested by Ricardo in 1919 (reference 25). Midgley in 1920 declined to accept the autoignition theory and held to the detonation-wave theory (reference 14). A year later Woodbury, Lewis, and Canby of the du Pont laboratories (reference 26) presented streak photographs of combustion in a bomb, taken by the method of Mallard and Le Chatelier (reference 27), and drew conclusions favoring the autoignition theory. These du Pont investigators seem to have regarded the detonation-wave theory as the one having had general credence up to that time. From an analysis of their streak photographs and from consideration of various facts reported by previous investigators, they concluded that "the possibility of detonation under such conditions [conditions existing in the engine cylinder] appears exceedingly remote." After mentioning that detonation is set up in a closed cylinder of small dimensions only with great difficulty, they further

stated: "On the other hand, autoignition of the high-density gases ahead of the flame front occurs over a wide range of fuel mixtures and conditions [in their tests] and gives a sudden development of pressure similar, in our opinion, to that characteristic of a knocking explosion. It is possible that this autoignition may set up detonation [a detonation wave] in some cases, thereby acting as an intermediate stage in knocking. Our experiments have not been carried to a definite conclusion, and present data do not warrant presentation of autoignition as a positive explanation for knocking. It is our feeling, however, that information at hand favors more strongly the theory of autoignition of the high-density gases ahead of the flame front than that of detonation [the detonation wave]."

Actual motion pictures of knocking combustion were first published in 1936 by Withrow and Rassweiler of General Motors Corp. (reference 28). These excellent photographs, taken at the rate of 2250 frames per second, showed the development of autoignition in the end gas and greatly increased the already existing confidence in the autoignition theory. They were taken at too low a rate to show a detonation wave, however, even though such a wave might actually have occurred after the autoignition that was photographed.

The autoignition theory, with the additional assumption of preflame chain reactions, has the advantage of explaining and correlating many of the known facts concerning knock. During the period of 1939 to 1945, however, urgent need for a modification of the simple autoignition theory of knock was shown by photographs of knocking combustion taken at the rate of 40,000 frames per second with the NACA high-speed motion-picture camera. The first of these photographs, presented in references 23 and 5, showed a reaction completed in 50 microseconds or less. The authors believed that this reaction was the true knock reaction because they could see in the projected motion pictures that this reaction occurred at the same time as the beginning of the violent vibration of the gases, which by then had come to be regarded as an indication of knock. Later NACA tests (reference 7) showed that this extremely quick reaction did occur simultaneously with the beginning of the vibrations. Serruys had previously (in 1932) concluded that knock generally occupies a time interval less than 100 microseconds in reference 29 and, in 1933, on a basis more in harmony with the standing-wave concept of knock, in reference 30. Considerations presented in the present paper have caused the author to abandon the exclusiveness of the concept "true knock reaction." The reaction will hereinafter be referred to as the "explosive knock reaction."

The need for a modification of the autoignition theory of knock lies in the fact that the evidence available in the literature indicates autoignition requires for its completion a time interval of an entirely higher order than the 50 microseconds involved in the explosive knock reaction, even under conditions of severity approaching those of the modern aircraft engine. The previously mentioned photographs by Withrow and Rassweiler (reference 28) clearly show brightly luminous autoignition occupying a time interval of the order

of 1000 microseconds. NACA high-speed photographs have shown autoignition flames slowly propagating themselves from point to point throughout the end gas before the explosive knock reaction occurs (reference 9); and another NACA high-speed photograph has shown autoignition developing slowly and simultaneously in all parts of the end gas before the occurrence of the explosive knock reaction (reference 5). These two types of autoignition shown in the NACA high-speed photographs, preceding the explosive knock reaction, occupied time intervals ranging from 500 to 1250 microseconds. Streak photographs were published as early as 1911 by Dixon and coworkers (references 31 and 32) showing slow autoignition in glass tubes resulting from quick compression. This autoignition progressed at a rate comparable with the rates of the autoignitions shown by Withrow and Rassweiler and by the NACA investigators.

The evidence showing that autoignition occupies a time interval of a higher order than 50 microseconds is not the only reason for believing simple autoignition to be an inadequate explanation of knock. Many investigations have shown that autoignition can occur without causing marked gas vibrations, which are probably the best known characteristic of knock in the present-day spark-ignition engine. These gas vibrations, if they occur, are visible in streak photographs taken by the method of Mallard and Le Chatelier (reference 27) as a series of bright bands extending across the photograph in a direction perpendicular to the direction of film movement. The gas vibrations also cause oscillations in pressure-time records.

Some excellent streak photographs presented by Withrow and Boyd (reference 33) are examples of nonvibratory autoignition in the engine cylinder. These General Motors investigators stated that both the pressure-time records and the flame traces show that the autoignition required 2° to 5° of crankshaft rotation (400 to 1000 microsec) for its completion. Figures 11 to 16 of their work clearly show the flame front traversing the greater part of the chamber at the normal rate and show the end gas then being consumed at a much higher rate. All of these figures except figure 14, however, reveal not the slightest indication of gas vibrations. It is difficult to conclude from the printed picture of figure 14 whether there is any evidence of vibrations. Moreover, the pressure-time records of figures 11 to 16 of reference 33 show no evidence of gas vibrations. Though audible gas vibrations probably did not occur in those tests, some kind of disturbing noise surely must have occurred, as is discussed in the present paper under "Detonation-Wave and Autoignition Theories Combined."

Withrow and Boyd did not comment on the absence of gas vibrations in their tests. Up to about the time of the writing of their paper (1931), gas vibrations do not seem to have been regarded as a usual feature of knock. The only recognized criterion of knock as seen in pressure-time records appears to have been simply a sharp increase in the rate of pressure rise. In 1932 Rassweiler and Withrow (reference 34) presented streak photographs clearly showing the gas vibrations; and in 1934 (reference 21) they showed that the vibrations as

seen in the photographs coincided, cycle by cycle, with fluctuations shown in the pressure-time records.

Woodbury, Lewis, and Canby in 1921 did not regard the gas vibrations as being associated with knock, for in the previously quoted passage (reference 26) they concluded on the basis of their own experiments that autoignition of the high-density gases ahead of the flame front gives a sudden development of pressure similar, in their opinion, to that characteristic of a knocking explosion. The pressure-time traces presented for the cases of autoignition referred to showed, in general, no gas vibrations but only a sharp increase in rate of pressure rise near the end of combustion. Almost without exception the streak photographs also showed no trace of gas vibrations; the exception was with ether-air mixtures. With initial temperature of 150° C and initial pressure of 65 pounds per square inch, neither the flame trace nor the pressure-time trace for an ether-air mixture showed any sign of gas vibrations, whereas with the same initial temperature and with initial pressure of 75 pounds per square inch, both the flame trace and the pressure-time trace showed the gas vibrations with agreement in frequency. The change that occurred in the phenomena studied in a bomb by these investigators, when passing from 65 to 75 pounds per square inch with ether-air mixture at 150° C, appears to correspond to the change in the recognized criterion of spark-ignition engine knock that developed in the early 1930's.

No particular note appears to have been made in the literature of the change in the recognized criterion of knock that developed in the early 1930's. Sufficient data do not appear to be available to explain the change or to indicate whether it was a real change caused by altered engine design and altered fuels or an apparent change developing with the securing of more extensive data.

In 1939 Boyd (reference 35) compared a streak photograph of autoignition without gas vibrations (fig. 10 of reference 35, same as fig. 16 of reference 33) and a streak photograph of autoignition with gas vibrations (fig. 12 of reference 35, same as fig. 10 of reference 34). He very reasonably regarded the case of his figure 12 as involving a much more violent knock than the case of his figure 10. Examination of his figures 10 and 12, however, discloses that the end zone was of nearly the same size in the two cases at the time the autoignition, or knock, occurred. The comparison therefore indicates that the violence of knock or at least the violence of the gas vibrations is not dependent on the size of the autoigniting end zone. Moreover, NACA high-speed photographs have shown plainly visible gas vibrations in cases where the end zone, if any existed at the time of start of the gas vibrations, was too small even to be seen in the photographs (references 6 and 7).

Other streak photographs showing autoignition without trace of gas vibrations may be found in papers by General Motors investigators (references 36 to 38). The most striking examples of this phenomenon, however, are to be found in the work of Duchene (reference 39). In this work many streak photographs are presented of combustion, with spark ignition, in a bomb equipped with a piston providing compression by

a blow from a heavy pendulum. Many of these flame traces show a sudden darkening extending entirely across the trace, which Duchene considered as indicative of a detonation wave. Only three of the records, however, 21, 35, and 36, show any trace of gas vibrations. In most cases the darkening is quite diffuse instead of practically instantaneous, as it should be if caused by a detonation wave. The records all distinctly show slow autoignition preceding the sudden darkening. The fraction of the total charge involved in the nonvibratory autoignition in the different records covers the entire range from near zero to practically the entire charge. Gas vibrations should not, of course, be expected from simultaneous autoignition of the entire charge at constant volume. Records 23, 28, 29, and 31 of Duchene's work, however, clearly show autoignition of about half the contents of the chamber without any trace of vibrations.

The inadequacy of simple autoignition as an explanation of the phenomenon of knock has been clearly recognized by some investigators. In 1928 Maxwell and Wheeler in reference 15 reported frequently observing autoignition flame, with 50-50 mixtures of pentane and benzene in a bomb, starting from the far end of the cylinder and progressing back to meet the spark flame. They reported that explosions in which this phenomenon occurred were no louder than usual and that the pressure records showed no unusual features. They concluded, in consequence, that such an ignition of unburnt residual mixture is not likely to be the cause of a pinking explosion in an engine cylinder. In reference 16 the same investigators stated: "Our objection to the 'autoignition' theory is that, when such ignitions occur during an explosion in a closed cylinder (for example, figs. 2 and 5), the explosion is no more violent than in their absence. Moreover, what we have termed a 'pink' in our cylinder, because it so closely resembles the pink in an engine cylinder, is obtained most commonly without the occurrence of 'autoignition.'"

In 1935 Egerton, Smith, and Ubbelohde (reference 17), in discussing the work of other investigators, stated: "'Autoignition,' that is, ignition in a region of the gas prior to the arrival of the flame front, was observed both in the knocking zone and elsewhere, but does not necessarily give rise to the knocking type of combustion, though it was supposed that the high rate of combustion in the knocking zone was due to autoignition within it."

In 1936 Boerlage (reference 19), in discussing the results of his own streak photographs, stated: "What surprised us, however, in the results obtained with the test engine, was the relatively slow character of the combustion due to autoignition. The development of the second center of ignition was at all points similar to the progression of the primary flame due to the spark. The 'simultaneous' combustion of the 'end gas,' which we have believed responsible for the knock, thus seems to be reduced to the rather calm development of a secondary center of ignition." He further stated: "* * * the velocity of the secondary flame front is practically equal at each instant to that of the primary flame front. We have never been able to make out any speed equal to the speed of sound, but at most, speeds of 150 meters per second, and

these only in the case of excessive detonation (knock). In the case of slight detonation (knock) the speeds do not attain even half this figure. * * * The pressure diagrams show only moderate pressure rises, and this is still another indirect proof of the fact that the speeds of the flames are relatively low and remain much below the speed of sound. We have not succeeded in demonstrating the existence of extreme local pressures."

The investigations mentioned have shown beyond possible doubt that autoignition can, and in many cases actually does, occur too slowly to cause the gas vibrations characteristic of knock. This fact does not prove that autoignition cannot, under any conditions, occur quickly enough to cause the gas vibrations. It does, however, preclude the possibility of regarding the occurrence or nonoccurrence of autoignition as a criterion for the occurrence or nonoccurrence of the type of knock characterized by gas vibrations. A different criterion must be sought, either the occurrence of autoignition at a rate above some critical value or the occurrence of some other phenomenon.

Indeed the criterion of autoignition at a rate above some critical value seems to be precluded by some of the NACA photographs (references 5 and 9), for in those cases slow autoignition was seen to occur, followed by the much faster reaction that set up the gas vibrations. In this connection it should be noted that some investigators (references 24 and 40) have regarded the apparent autoignition shown in one of the NACA papers (reference 5) as a preflame reaction. The slow apparent autoignitions shown in reference 9, however, are more difficult to explain as preflame reactions because they propagate themselves from point to point in the same manner and at about the same speed as a normal flame.

The available literature, as reviewed in this section, points to the conclusion that some phenomenon other than simple autoignition must be sought as the cause of the gas vibrations associated with knock in the modern spark-ignition engine.

Detonation-wave theory.—Prior to the NACA investigations that will be summarized in the present paper the occurrence of a detonation wave in a bomb or a knocking engine had not been supported by any such abundance of direct experimental evidence as the occurrence of autoignition. This fact is, of course, readily explained by the consideration that the detonation wave, being a many times faster phenomenon than autoignition, requires very much more powerful methods for its detection. A very important consideration in favor of the detonation wave as the explanation of gas vibrations is the unquestionable fact that it would cause gas vibrations if it did occur, whereas it has been shown that simple autoignition does not necessarily cause the vibrations when it occurs.

Many writers have long been strongly opposed to the detonation-wave theory of knock, principally because it is very difficult to set up detonation waves in containers as small as an engine cylinder, or indeed in hydrocarbon-air mixtures at all, and because many variables have unlike effects on the tendency of a combustible charge to knock in an engine and to develop a detonation wave in a tube.

In 1936 the Russian investigators Sokolik and Voinov (reference 18) furnished direct experimental evidence of propagated combustion, as contrasted with the concept of simultaneous autoignition, traveling through the end zone in a knocking engine at the correct speed to be regarded as a detonation wave. This evidence is in the form of streak photographs for which a sufficiently high film speed was used to resolve the slope of the luminosity front developed by the detonation wave. It is unfortunate that this work has not, in the past few years, received more careful consideration. The photographs of Sokolik and Voinov were taken through a narrow window extending across the combustion chamber in the direction of the flame travel. The results show the flame traversing the greater part of the chamber at a mean velocity usually less than 20 meters per second, then traversing the remaining part of the chamber at a velocity of the order of 2000 meters per second.

The photographs of Sokolik and Voinov are, of course, open to the criticism that they show the performance of only a narrow zone in the combustion chamber. For this reason, the illusion of a detonation wave traveling at 2000 meters per second could have been caused by a much slower autoignition traveling through the end gas at a considerable angle to the visible zone. Such an illusion should not be expected to be consistent throughout many records. Sokolik and Voinov, however, do not state how many records they studied.

NACA high-speed motion pictures of knock in references 6, 7, and 11 have suggested that the explosive knock reaction does not necessarily originate in the flame front but that it originates at random anywhere within the normal flame or the autoigniting end gas. For this reason NACA investigators have been slow to accept the results of Sokolik and Voinov as having general validity, suspecting that some difference in test conditions may have caused a type of knocking phenomenon to occur in their work different from any knocking phenomenon that has been found in the NACA investigations.

The new evidence for the occurrence of a detonation wave in the knocking engine, based on the high-speed and ultra-high-speed photographs of references 10 and 11 will be discussed in the second part of the section called "Discussion and Analysis."

Intermediate flame velocity.—Intermediate between the slow autoignition found by various investigators and the detonation-wave velocity determined by the Russian investigators in reference 18 is the finding by Schnauffer (reference 41) of a speed of 265 to 300 meters per second for the travel of a flame through the end zone in knock. Schnauffer made this determination by means of ionization gaps mounted in different parts of the combustion chamber. The ionization current across the successive gaps was amplified and used to light neon bulbs. The time interval between the lighting of the successive bulbs was measured by the record of the bulbs on a photosensitive drum rotating at high speed.

Flame travel at 265 to 300 meters per second through an end zone 2 to 3 centimeters long would be almost fast enough to satisfy the 50-microsecond limitation imposed by the

NACA photographs (reference 5), and such a rate of flame travel might, therefore, very well be regarded as a satisfactory cause of the explosive knock reaction. Note should be made, however, that the speed of 265 to 300 meters per second has not been verified by other investigators. Schnauffer did not indicate how many ionization gaps were used in the actual knocking zone to determine the velocity of 265 to 300 meters per second. Examination of the pattern of the gap locations as shown in the figures of his paper indicates either that the velocity was determined from the time interval between ionization of only two gaps or that the distance over which the velocity was measured was much greater than 2 or 3 centimeters, in which case the 50-microsecond limitation was not satisfied. Measurement of rate of flame travel on the basis of the time interval between ionization of two gaps would not be valid in case of any type of greatly accelerated reaction in the end gas. In such a case the normal flame travel through an indeterminate fraction of the distance between the last two gaps would be erroneously treated as the flame travel across the entire distance; the result would be a meaningless velocity.

In Schnauffer's paper oscillograph records were shown for the ionization currents produced both by the normal flame and the knock reaction in the end zone. The oscillograph records for the two types of combustion look very much alike. Hastings has shown in reference 42, with the vibratory type of knock, that the total time interval throughout which ionization currents are measurable in the end gas is only a small fraction of the time interval throughout which the ionization currents are measurable in the earlier-burned parts of the cylinder charge. The similarity in the oscillograph traces of Schnauffer's work therefore indicates that he was dealing with simple autoignition, not vibratory knock.

Nature of gas vibrations.—Many investigators have shown the occurrence of gas vibrations in bombs and in engine cylinders, both by photography and by pressure-time records. When the vibrations were first observed on indicator records of engine combustion, the question was raised whether they were not natural vibrations of the indicator set up by the blow of knock. Undoubtedly in many cases of simple autoignition this explanation was correct. In this connection the observation by Schnauffer in 1931 (reference 43) is of interest. With the ionization-gap method he found apparently simultaneous ignition of end gas amounting to approximately 50 percent of the entire cylinder charge; the indicator record showed no vibrations but only a sharp increase in rate of pressure rise. Schnauffer commented: "Figures 4 and 5 show that with a pressure indicator sufficiently free of inertia it is very well possible to record the knocking blow without the appearance of pressure oscillations. It is thereby demonstrated that the oscillations are not pressure oscillations." When Withrow and Rassweiler in 1934 (reference 21) showed a precise agreement between the oscillations recorded by an indicator and the bright bands on a streak photograph of the combustion, it was no longer possible to doubt the validity of the vibrations recorded by the best indicators.

Examination of the published records of gas vibrations in bombs and in engine cylinders reveals that with comparatively slow-burning mixtures, such as are used in the spark-ignition engine, these vibrations are generally of two types: With the first type the first cycle of vibration recorded has a larger amplitude than any of the later vibrations and the decay of the vibrations is gradual; with the second type both the buildup and the decay of the vibrations are gradual. A detonation wave, by definition, would cause the first type of vibration but not the second. With auto-ignition ruled out as a cause of the first type of vibration, the detonation wave is probably the only known physical phenomenon that could cause it. This type of vibration will, therefore, be referred to hereinafter, for convenience, as the "detonation wave" type of vibration. The many investigations that have shown the detonation-wave type of gas vibration in bombs or engine cylinders, either photographically or by means of pressure indicators, include some of those previously mentioned (references 5 to 7, 18, 21, 26, 30, 34, 35, and 38), as well as investigations by Souders and Brown (fig. 6 of reference 44), Boerlage, Broeze, van Driel, and Peletier (reference 45), and Rothrock and Spencer (reference 46).

The type of vibration having a gradual buildup obviously requires a gradual feeding in of energy over a period of many cycles. This gradual feeding in of energy could occur only if the vibrations themselves affected the local rates of combustion, or energy release, in such manner as to speed up the combustion in the high-pressure regions relative to the low-pressure regions. Such an effect would cause any slight accidental vibration to become self-amplifying. The cause of an accidental vibration is not hard to find. Ignition at a point in a vessel will unavoidably send forth a pressure wave which, after reflection from the far wall, will return to the point of ignition and may speed up the combustion upon its arrival. Souders and Brown at the University of Michigan (reference 44) found that a very pronounced occurrence of this type of vibration could be eliminated by shortening their spark commutator contact so as to decrease the intensity of the pressure disturbance at ignition. The type of gas vibration having a gradual buildup will be referred to hereinafter as the "vibratory combustion" type of vibration.

The possibility, of course, exists that the inertia and damping characteristics of a pressure indicator might cause it to indicate a gradual buildup of vibrations even though the gas vibrations actually were of the detonation-wave type, particularly in cases where the vibration frequency is nearly the same as the natural frequency of the indicator. The failure of such spurious records to occur in practice, however, is indicated by the fact that all the records to be found in the literature fall very distinctly into the detonation-wave or the vibratory-combustion type; there is apparently no middle ground. A middle ground would be expected when the detonation-wave type of vibration is

modified by a pressure indicator with only slightly too much inertia to produce a faithful record.

The vibratory-combustion type of vibration, as should be expected, generally occurs in fairly long cylindrical bombs, in which the natural frequency is comparatively low and the total time of flame travel is comparatively long. Under such conditions this type of vibration may occur without any evidence of autoignition, hot-spot ignition, or any other type of combustion except the normal flame from the igniting spark, as in the previously mentioned work at the University of Michigan (figs. 5, 7, and 13 of reference 44).

Gas vibrations of the vibratory-combustion type in bombs have also been shown by Hunn and Brown, Kirkby and Wheeler, Lorentzen, Duchene, Wawrziniok, and Köchling in references 47, 48, 49, 39, 50, and 51, respectively. The photographs by Kirkby and Wheeler show how the vibratory combustion requires a bomb of considerable length. Lorentzen pointed out that the vibrations, which he apparently believed were caused by the same phenomenon as knock in the engine cylinder, could not have been caused by detonation because they set in before the attainment of maximum pressure. The vibrations shown by Duchene (records 21, 35, and 36) are of particular interest because they developed long after the charge had been completely inflamed, yet appear to have been built up gradually. The work by Wawrziniok showed gradual buildup not only of the vibrations in a bomb but also of the air vibrations outside a knocking engine. It is possible, however, that the forced vibrations of the engine walls built up gradually even with a detonation-wave type of gas vibration in the combustion chamber. The gradual buildup of the air vibrations in this case was very rapid as compared with the buildup of the gas vibrations in the bomb; in fact, this case seems to be the middle ground that is lacking in indicator records exposed directly to gas vibrations within the combustion chamber.

The work of Maxwell and Wheeler (references 15, 16, and 52) seems unique in the fact that they appear to have encountered both vibratory combustion and the detonation-wave type of vibration in the same explosion, and the one occurring just before the end of the flame travel and the other just after the flame front reached the far wall of the bomb. There seems to be no reason, however, why the two types of vibration should not occur, one after the other in the same combustion cycle. Moreover, two independent vibrations, each of the detonation-wave type, can be set up one after the other in the same combustion cycle, as has been shown in reference 9.

The excellent streak photographs by Payman and Titman (reference 53) are probably not pertinent to the present discussion because they involve only much faster-burning mixtures than are ordinarily used in spark-ignition engines. Inasmuch as pressure-time records are not included with the photographs by Payman and Titman, any discussion of the type of vibration set up by the phenomena shown in those pictures would be only speculation.

Detonation-wave and autoignition theories combined.—

The foregoing discussion clearly indicates a need for some kind of combination of the detonation-wave and autoignition theories of knock, inasmuch as the occurrence of both autoignition and an apparent detonation wave has been demonstrated in the knocking engine. The combined theory proposed herein involves an affirmative decision on the controversial question as to whether afterburning takes place in a volume of gas for a considerable time after the flame front has passed through that volume of gas, or after the entire volume of gas has become inflamed through autoignition. For the purpose of this discussion "afterburning" will be understood to mean continued oxidation of combustible or any other reaction that causes continued spontaneous expansion of gases or pressure increase at constant volume.

If the concept is accepted of a body of end gas inflamed throughout its entire volume by autoignition, then it would seem reasonable that under severe conditions such an inflamed body of gas might be highly susceptible to the propagation of a detonation wave and that a detonation wave traveling through the inflamed body of gas might be the immediate result of autoignition. Such a high susceptibility to the detonation wave might be caused not only by the high temperature within the inflamed gases but by high concentrations of molecular fragments that might be of importance in the propagation of the detonation wave. If the possibility is accepted of a detonation wave traveling through a body of gas previously inflamed by autoignition, it seems almost necessary also to accept the possibility of such a wave traveling through a body of gas in which afterburning is taking place behind the normal flame front. In this manner a detonation wave could develop without autoignition after the entire contents of the combustion chamber had been ignited by the normal flame front. Larger volumes of inflamed gas at any one instant would be expected, however, with autoignition than without autoignition; therefore, a detonation wave should be expected to develop principally in the autoigniting end gas rather than in afterburning gas behind the flame front.

Concerning the possibility of burning after passage of the flame front through a body of gas, Withrow and Rassweiler in reference 36 concluded that the spectrum of the afterglow emitted by such supposedly afterburning gas is the same as that emitted during the CO-O_2 reaction and caused by active CO , O_2 , CO_2 , or O_3 molecules. They suggested that the $\text{H}_2 + \text{CO}_2 \rightleftharpoons \text{CO} + \text{H}_2\text{O}$ reaction is in equilibrium after the flame front has passed and that the afterglow is due to a readjustment of the equilibrium when the pressure and consequently the temperature are increased. They remarked: "The distribution of intensity of the afterglow throughout the combustion chamber accords well with the idea that the emission is by carbon dioxide heated by the increase in pressure brought about by combustion of the rest of the charge."

The suggestion that afterglow is entirely caused by readjustment of equilibrium due to compression does not seem

compatible with the results of Stevens' work at the National Bureau of Standards with a soap-bubble bomb in which no appreciable compression of the earlier-burned gas by the later-burned gas was possible. Some of Stevens' streak photographs show very considerable afterglow (references 54 to 56). On the other hand two of his photographs (references 57 and 58) show only the trace of the luminous flame front without afterglow.

Other sound explanations of the afterglow may exist independent of the concept of afterburning, but the possibility of other explanations only precludes use of the afterglow as support for the afterburning hypothesis; that is, the possibility of such explanations may not be regarded as evidence against afterburning.

Lewis and von Elbe in reference 59 have regarded Stevens' results (references 56 and 57) as evidence against the concept of afterburning, stating "* * * thousands of explosions * * * failed to reveal the slightest indication of further expansion of the burned sphere after the flame had traveled across the entire gas mixture." If close measurements are made on figure 2 of Stevens' 1923 report (reference 54) and figure 2 of his 1930 report (reference 56) it seems questionable whether a positive statement can be made that these figures show not even the slightest continued expansion of the luminous zone after the constant-velocity expansion of the spherical shell of flame had come to an end. (The end of the constant-velocity expansion of the flame shell seems to be the only means of determining from the photographs when the flame "had traveled across the entire gas mixture.") In one of the flame traces of figure 4 of reference 58 in which the afterglow is absent, continued expansion is plainly visible after completion of the constant-velocity expansion of the flame shell. The printed reproductions of photographs in reference 55 show the flame-front trace too indistinctly for judgment on continued expansion after completion of the constant-velocity expansion. Figure 2 of reference 54 shows luminosity fading progressively from the outer edge of the luminous sphere toward the center after some slight expansion has possibly taken place; the progressive fading is probably caused by rapid cooling of the outer shell of hot gases after the combustion is nearly complete. Figure 4 of a report by Randolph and Silsbee (reference 60), obtained with the same Bureau of Standards apparatus as used by Stevens, shows continued expansion most distinctly after completion of the constant-velocity expansion. A consideration that must always be given attention in Stevens' photographs, as well as in all photographs taken by flame radiations, is the fact that these photographs may not represent the true flame front because of low luminosity in the early stages of burning and because of the finite exposure time required to make a record on the photosensitive material.

The experimental work reported and the arguments advanced by Lewis and von Elbe in reference 59 were concerned mainly with the question of whether combustion in a constant-volume bomb is complete at the time peak pressure is reached and not with the question of whether peak pressure is reached at the instant the flame front has passed through

the last increment of gas. The afterburning required by the proposed combined detonation-wave and autoignition theory would cover a time interval of an entirely lower order than that considered in the question of whether combustion is complete at the instant of maximum pressure. The only consideration offered by Lewis and von Elbe, other than the photographs of Stevens, that would have a bearing on the question of afterburning on the smaller time scale is the suggestion that with afterburning the sharp breaks obtained with fast-burning mixtures between the rising pressure curve and the cooling curve would not occur. By the same token it might be suggested that the extremely flat pressure maxima of slower-burning mixtures, such as shown in figure 16 of reference 7, would not occur if there were no afterburning.

Probably the strongest experimental evidence against afterburning is the work presented in papers by General Motors investigators. Tests with a sampling valve (reference 61) showed that free oxygen disappeared from the charge immediately after passage of the flame front, but this evidence is open to the question of whether burning was not completed after the gases were removed from the combustion chamber by the sampling valve. The General Motors investigators also checked flame-front positions as shown by high-speed motion pictures against pressure rise obtained from indicator records. (See references 62 to 64.) The results indicated completion of burning at the flame front, with some exceptions in reference 64. This evidence is open to the previously mentioned objection that the photographs may not show the true flame front. The agreement between flame-front positions as shown by the photographs and as calculated from the pressure records on the assumption of complete combustion in the flame front may be a coincidence or the greater part of the combustion may actually be completed in a very small part of the deep combustion zone.

That the General Motors photographs may not actually have recorded the true flame fronts is indicated by some of the NACA schlieren photographs of reference 7. In this work it was shown that peak pressure was reached, at top center, very nearly at the same time that the schlieren flame pattern completely disappeared from the high-speed motion pictures, or about 10° of crank angle at 500 rpm after the flame front had completely filled the chamber. This finding that peak pressure at constant volume coincides with the final fadeout of the schlieren flame pattern is supported by the previous demonstration of the same fact in a bomb by Lindner (reference 65).

Other evidence in favor of the concept of afterburning has been furnished by various investigators. The ionization records obtained by Hastings (reference 42) showed ionization persisting over 20° to 30° of crank angle at 2000 rpm with normal combustion. With his records of ionization in the end zone during knock, the persistence had only a fraction of that magnitude. He attributed the difference to the much faster combustion in the end zone during knock. It is of interest, in Hastings' records of ionization with normal combustion, that the ionization did not decrease steadily after passage of the flame front but irregularly with even several sharp increases in ionization after the original passage of the flame front.

Souders and Brown (reference 44) with their streak photographs and simultaneous pressure records of combustion in a constant-volume bomb noted an appreciable increase in pressure after the flame front reached the end of the bomb. Marvin and Best (reference 66), observing flame stroboscopically through small windows mounted in a cylinder head, reported pressure rise after complete inflammation of the charge with very low compression ratios. Wawrziniok in reference 55 found maximum pressure developing in his bomb considerably after the flame front had ionized a gap at the end of the bomb. In this case the ionization gap was located at the most distant position in a hemispherical end of the bomb so that error due to curvature of flame front was minimized; yet the lag between ionization of this gap and peak pressure was about 20 percent of the total burning time. Marvin, Caldwell, and Steele (reference 67) observed that total radiation from burning gases increased after inflammation throughout a time interval equivalent to about 20° of crankshaft rotation at 600 rpm.

Bureau of Standards investigators (reference 68), taking streak photographs of combustion in a spherical bomb, suspended fine grains of gunpowder at various points on a diameter of the bomb by means of human hairs. With central ignition, the brilliantly burning grains of gunpowder continued to move toward the center of the bomb for some time after the flame reached the wall of the bomb. This experiment seems to be particularly strong evidence of afterburning in the outer parts of the bomb.

Lewis and von Elbe have done work determining the temperature zones in burner flames in reference 69. Much uncertainty would be involved, however, in applying the results to the much different conditions existing in engine combustion.

In a discussion of combustion in a turbulent stream (reference 70) Shelkin has drawn a model of flame structure that might well apply under the highly turbulent conditions existing during combustion in the engine cylinder. According to this model, the turbulence in the flame front causes the flame to advance in microscopic, or near-microscopic, tongues. The structure behind the flame front is cellular; the cell walls constitute burning gas and the interiors of the cells constitute unignited gas. According to this model, the unignited gas within each cell is gradually consumed as the flame front progresses beyond the cell. With this structure, in the microscopic sense the burning zones might all be very thin; in the microscopic sense a deep afterburning zone would exist beyond the flame front. In any event, the preponderance of experimental evidence available at this time appears to favor the existence of a rather deep zone of combustion behind the flame front in the engine cylinder, though the main part of the combustion may take place only within a small part of this zone. Whether the combustion zone is cellular on the microscopic scale or only on a submicroscopic molecular scale does not seem important in the presentation of the combined theory of knock. In either case there is a possibility that the gases in the combustion zone may be peculiarly susceptible to the propagation of a detonation wave, and the available evidence on this point should be carefully considered.

The concept of autoignition followed by the development of a detonation wave was given passing attention in the previously quoted remarks of Woodbury, Lewis, and Canby in reference 26. Among the streak photographs of autoignition resulting from quick compression of the charge in a glass tube presented by Dixon and his coworkers (references 31 and 32) were included some records of what they believed to be detonation waves. Dixon and his coworkers pointed out the fact that the development of the detonation wave was always preceded by autoignition at some point within the charge. The concept of the development of a detonation wave in autoigniting end gas has also been suggested by Boerlage and van Dyck in reference 71. They pointed out that "simultaneous combustion" at the beginning should be considered as a slow pressure rise in comparison with "true detonation" but that it ultimately may have the same character. The reverse concept, autoignition triggered by a shock wave, has been suggested by Dreyhaupt in reference 72.

The concept of autoignition followed by the development of a detonation wave is consistent with the high-speed motion pictures presented in various NACA reports (references 5 to 9) if the explosive knock reaction is considered to be a detonation wave. In these photographs, in most cases where end gas was visible at the time of the explosive knock reaction, this reaction has been preceded by some form of apparent autoignition. In one case the apparent autoignition developed at definite centers within the end gas and spread out in all directions from those centers to fill the end zone before the explosive knock reaction occurred. (See fig. 10 of reference 9 on preknock vibrations.) In another case the autoignition began at the chamber wall and propagated throughout the end zone before the explosive knock reaction occurred. (See fig. 12 of reference 9.) In this case the visible explosive knock reaction was light. In other cases the autoignition developed uniformly and simultaneously throughout the end zone before the explosive knock reaction occurred. (See fig. 5 of the preliminary report, reference 5.) In yet other cases autoignition was not clearly visible in the photographs but a visible vibration of the gases of the detonation-wave type was set up before the explosive knock reaction occurred (reference 9). The occurrence of a visible vibration before the explosive knock reaction is an effect apparently not frequently encountered. It appears likely that this phenomenon is comparable with the explosive knock reaction in speed and it may, therefore, be a mild detonation wave followed later by the development of a many-times more-powerful detonation wave.

The evidence of the NACA high-speed schlieren photographs of references 5 to 9 is open to the criticism that the end-zone reactions shown before knock may not represent true flame because the schlieren system may reveal reactions much less intense than flame combustion. The same phenomenon has been shown, however, in photographs exposed by direct flame radiation presented by Rothrock and Spencer (reference 46). With 18- and 30-octane fuels at a compression ratio of 7, photographs taken at about 2000 frames per second (fig. 7 of the report by Rothrock and Spencer) showed autoignition in the end gas one frame before the development of the brilliant illumination caused by

knock. In the same paper Rothrock and Spencer showed that this brilliant illumination coincided chronologically with the beginning of the gas vibrations.

The concept of a detonation wave set up in afterburning gases behind the normal flame front has been proposed previously by Maxwell and Wheeler in references 15, 16, and 52. In streak photographs of combustion in a bomb with knocking fuels they found only very faint afterglows behind the flame front during the travel of the flame through the bomb. After the flame had traveled completely through the charge they observed an extremely high-speed travel of a more brilliant glow through the chamber. With non-knocking fuels, however, the afterglow behind the normal flame front was brilliant. They reported invariably a correlation between the pinking tendencies of fuels and the lack of brilliancy in the afterburning, and they reported that the addition of ethyl ether or amyl nitrate to a fuel decreased the brilliance of the afterglow, and that decomposed tetraethyl lead increased the brilliance of the afterglow. These investigators concluded in part that the tendency to knock was dependent on slow afterburning, leaving sufficient energy behind the flame front to maintain a shock wave (detonation wave) set up by collision of the flame front with the chamber wall. Lorentzen in reference 49 found evidence from experiments with a combustion bomb that he believed supported the theory proposed by Maxwell and Wheeler. The finding that knocking fuels show less brilliant afterglows than nonknocking fuels has been verified by Duchene (reference 39) and by Rothrock and Spencer (reference 46). Rothrock and Spencer have also presented in figure 12 of the same paper 2000-frame-per-second motion pictures of combustion of 65-octane gasoline in which the combustion chamber was entirely inflamed before the occurrence of knock, as indicated by very brilliant reillumination of the entire chamber. In figure 4 of one of the NACA reports (reference 6) a knocking reaction is seen to have occurred not only after complete inflammation of the cylinder charge but even so late that the schlieren combustion pattern was almost gone.

The combined detonation-wave and autoignition theory, to be complete, must account for the fact that combustion cycles involving nothing more than simple autoignition have been found by General Motors investigators in references 33, 36, and 37 and have been regarded by those investigators as knocking cycles. It is clear that gas vibrations can cause forced vibrations of the combustion-chamber walls of the same frequency as the gas vibrations and thus cause a high-pitched ping. As gas vibrations apparently did not occur in the combustion cycles reported in those papers, however, the question naturally arises as to the cause of the knock that was heard. The only possible answer appears to be that the knocking sound was due to natural vibrations of engine parts.

The autoignition that occurred in the General Motors investigations has been seen to require a period of approximately one-thousandth part of a second for its completion. The sharp increase of pressure in the combustion chamber within the period of one-thousandth part of a second could set up natural vibrations in some of the stressed engine

parts. The energy imparted to the natural vibrations by the autoignition would, in general, be greater in the case of low-frequency vibration than in the case of high-frequency vibration. The influence of vibration frequency on the energy imparted to the vibration by the autoignition could be determined mathematically only if definite information were available as to the rate at which energy is released by autoignition at each instant throughout the autoignition process. Though no such information is available, the experimental evidence at least indicates that energy is released by the autoignition in such a manner that it does not excite appreciable vibration of the gases. It may, therefore, be reasonably assumed that the autoignition would excite natural vibrations of the stressed engine parts only in such modes as have a natural frequency considerably less than the natural frequency of the vibrating gases.

The suggestion that knock is due to vibration of engine parts caused by autoignition and that pink is caused by gas vibrations had previously been made by Boerlage and his coworkers (references 19, 45, and 71).

Summary of literature-based argument for combined knock theory.—The following facts appear to be supported by the weight of experimental evidence:

1. Autoignition of comparatively large bodies of end gas occurs too slowly under certain conditions to produce audible gas vibrations.
2. Under suitable conditions one or both of two types of gas vibration may occur, the detonation-wave type and the vibratory-combustion type.

3. Either type of gas vibration may occur independently of autoignition, but under some conditions the detonation-wave type of gas vibration tends to occur very soon after slow autoignition has taken place.

4. Under suitable conditions apparent detonation waves can develop in the engine cylinder.

5. Under a wide range of conditions, either combustion continues for a distance sometimes as great as several inches behind the flame front or some adjustment of equilibrium takes place through the same distance, resulting in increased pressure, continued ionization, and continued emission of light.

The foregoing facts, supported by the experimental evidence, suggest the following explanation of knock in the spark-ignition engine:

(a) Knock of a comparatively low pitch is caused by simple autoignition of end gas at a rate too slow to produce audible gas vibrations.

(b) Knock involving both low- and high-pitched tones may be caused by autoignition followed by the development of a detonation wave in the autoignited gases.

(c) Knock of high pitch may be caused by a detonation wave in afterburning gases behind the flame front. This detonation wave, having originated in the afterburning gases behind the flame front, may also pass through unignited end gas.

This explanation of knock harmonizes with the findings of the NACA photographic knock investigations that will be summarized in the second part of this section.

FIGURE I-1.—Old combustion apparatus.

FIGURE I-2.—Full-view combustion apparatus.

REPORT OF FINDINGS OF NACA PHOTOGRAPHIC KNOCK INVESTIGATIONS

Apparatus and operating conditions.—The high-speed motion pictures presented and discussed herein have in part been selected from previously published data (references 5 to 11) obtained with the high-speed and ultra-high-speed motion-picture camera (references 1 to 3) and the NACA combustion apparatus. Most of the work was done with the old combustion apparatus described in references

5 and 46. A small part of the work was done with a newer combustion apparatus. A diagrammatic sketch of the old combustion apparatus is shown in figure I-1; the newer apparatus in figure I-2. The old combustion apparatus is a single-cylinder engine of 5-inch bore and 7-inch stroke, with glass windows in the cylinder head and a glass mirror on the piston top, as shown in the figure. The visible part of the combustion chamber is $4\frac{1}{2}$ inches long, as shown at

FIGURE I-3.—High-speed photographs of normal nonknocking combustion in spark-ignition engine. Fuel, S-1; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; one spark plug; spark timing, 20° B. T. C.

frame G-20 in figure I-3. The newer combustion apparatus (fig. I-2) was designed to provide a view of the entire combustion chamber. This engine has a bore of $4\frac{1}{2}$ inches and a 7-inch stroke. Air for combustion is forced into the cylinder through ports uncovered by the piston at the bottom of its stroke and escapes through other ports on the opposite side of the cylinder. The pressure before the start of compression in this engine is controlled by means of the back pressure applied outside the escape ports.

The optical arrangements for schlieren photography (references 5 and 11) will not be redescribed herein, except to state that with each of the combustion apparatus the schlieren photographs were taken by externally supplied light projected into the combustion chamber through the glass windows and then reflected back out through the glass windows to the high-speed camera by the mirror on the piston top.

In all the investigations in which the combustion apparatus has been used, the engine has been driven by an electric motor and operated under its own power for only one combustion cycle in each run; in each case the entire series of photographs was taken during the single combustion cycle. Solid injection of fuel was used and fuel was injected only for the single power cycle. With the old combustion apparatus the fuel was injected on the inlet stroke; with the newer full-view apparatus it was injected early in the compression stroke. The engines were heated prior to the motoring period and kept hot during the motoring period by the circulation of heated glycerin through the cooling passages of cylinder and head. All of the investigations have been made with glycerin temperature approximately at 250°F leaving the cylinder and head. The investigations have all been made with an engine speed of approximately 500 rpm. Spark timings and spark-plug positions were selected to produce knock at top center with the end gas usually well within the field of view. Other engine operating conditions and the fuels used will be stated in the discussions of the individual tests. Atmospheric intake was always used with the old combustion apparatus.

Normal nonknocking combustion.—Figure I-3 of this paper is a reproduction of figure 3 of the preliminary report (reference 5). This figure shows the normal process of smooth nonknocking combustion. Only one spark plug was used, in E position. (See fig. I-1.) The injection valve was in J position. (See fig. I-1.) The fuel was S-1 reference fuel; spark timing, $20^{\circ}\text{B. T. C.}$; compression ratio, 7.0; and fuel-air ratio, approximately 0.08.

Throughout this paper the individual frames of figure I-3 and other figures will be referred to as frame A-1, meaning the first frame of row A, frame D-8, meaning the eighth frame of row D, and so on. The order in which the pictures were taken is from left to right through the first row, frame A-1 through frame A-20, then from left to right through the second row, frame B-1 through B-20, and so on.

In the first few frames of row A of figure I-3 the flame from the igniting spark is just coming into view. A large black spot appears at the upper left-hand corner of each of these frames. This large dark spot is due to an imperfection in the schlieren system and has nothing to do with the combustion. The flame coming into view in these frames is barely visible as a small dark spot at the central upper edge

of each frame. The increase in size of the flame between one frame and the next is extremely small because the time interval involved is only $1/40,000$ second, that is 25 microseconds. The flame very gradually grows larger throughout the first five rows of frames, A to E. In frame E-10 the flame has grown until it covers almost the upper half of the frame as a dark mottled cloud. Although these photographs are actually positive prints, the flame is seen as a dark mottled cloud because of its effect on the externally supplied light. The photographs were taken too fast, and the lens aperture was too small, for the flame to be photographed by the light radiated by it. The burning region appears to scatter the externally supplied light so that it does not get through to the camera lens. The burning region consequently shows up as a dark cloud in contrast with the areas where no combustion is proceeding. The externally supplied light passes through the nonburning areas uninterrupted to the camera lens and causes a fairly uniform white appearance of these areas in the positive prints. For reasons that will be explained it is believed that all of the dark mottling visible in the upper half of frame E-10 is indicative of continuing combustion. In this frame, therefore, the apparent depth of the flame in the direction of flame travel is approximately 2 inches. It is not known to just what extent this apparent depth is real and to what extent it is caused by tonguing of the flame. To explain the apparent depth entirely on the basis of flame tonguing, however, would require a quite illogical assumption that the flame is always much more extensively tongued in the planes that cannot be seen in the photographs than in the plane that is seen in the photographs. (The distance through the combustion chamber in the line of sight from the surface of the mirror on the piston top to the under surface of the inner glass window is approximately 1 in.) The appearance of frame E-10 of figure I-3 is quite typical of this stage of combustion in all photographs taken under the same conditions. The leading edge of the flame as seen in frame E-10 is somewhat irregular but does not show any such pronounced tonguing as would be required to explain the presence of mottling throughout the entire area behind (above) the flame front.

In the frames of rows F, G, and H the flame front slowly advances downward to a position (in frame H-20) about two-thirds of the way across the chamber from the point of ignition. At the same time the dark mottling disappears throughout most of the area behind (above) the flame front, so that in frame H-20 the apparent combustion zone extends only a short distance backward from the flame front. This narrowing of the combustion zone as the flame front travels through the central part of the chamber is also typical of the photographs taken under these conditions. In the frames of rows I to M the flame front slowly completes its travel to the extreme end (lower end) of the combustion chamber. After the flame front reaches the extreme end of the chamber in frame M-20, the mottled combustion zone gradually dissolves in the frames of rows N, O, and P, leaving a clear white field throughout the entire area of the chamber in frame P-20.

It may be noted that the dark spot which was visible in the upper left-hand corners of the early frames of row A is not visible in the frames of row P. This spot, caused by

imperfection of the optical system, moved about because of rocking of the piston at top center and had moved completely out of the field of view in the frames of row P.

From the standpoint of a study of knock, the most important feature of the normal combustion photographs of figure I-3 other than the apparent depth of the combustion zone is the fact that all stages of the combustion process appear slow and smooth. When the photographs are projected on a motion-picture screen the entire process is slowed down so that it resembles the motion of a storm cloud. After the combustion is completed and the mottled zone has faded out the gases in the combustion chamber are very quiescent, a condition contrasting decidedly with the appearance after a knocking combustion.

Nonknocking combustion with preignition from hot spot.—Figure I-4, a reproduction of figure 7 of reference 5, shows a combustion process with the same fuel and the same engine operating conditions as those of figure I-3 but with ignition from a hot spot as well as from the spark plug. The spark plug was again in E position (see fig. I-1), but an electrically heated coil was inserted by means of a special plug at F position (see fig. I-1) and the current through this coil was adjusted to such a value that the coil would ignite the fuel-air mixture at an earlier time than the igniting spark at the plug in E position.

When the camera shutter opened for the shot of figure I-4, in the first few frames of row A, the flame from the hot spot had already come well into the field of view. The flame from the spark plug comes into view in the later frames of row E and the earlier frames of row F, visible at the top of each frame as a whitish spot. In this case the flame shows up white by contrast with the dark spot caused by the imperfection of the schlieren system. When the flame gets well out into the white part of the field of view in row J it again shows up as a dark mottled region as in figure I-3. The flame from the spark plug and the flame from the hot spot merge in the frames of rows J and K and the mottled combustion zone very gradually dissolves in the frames of rows L to P. In this case in the frames of row P the dark spot at the upper left-hand corners of the frames, caused by imperfection of the schlieren system, is still visible. Again it has no significance relative to the combustion process.

From examination of the photographs of figure I-4 as stills, as well as from observation of these photographs as a motion picture projected on the screen, it must be concluded that the entire combustion process is just as smooth and gradual as with the normal nonknocking combustion process of figure I-3. After the mottled combustion zone has faded out the gases again appear very quiescent, in contrast with the appearance after a knocking combustion. The photographs of hot-spot ignition clearly show that this type of ignition is not a direct cause of knock.

Preliminary view of knock.—Figure I-5 of this paper is the same as figure 5 of reference 5 and the same as figure 2 of reference 10. The combustion process shown in this

figure involves one of the most violent knocks ever photographed. The engine operating conditions were the same as those for the normal nonknocking combustion process shown in figure I-3. Instead of S-1 fuel, however, a blend consisting of 50 percent S-1 and 50 percent M-2 reference fuels was used.

The flame from the igniting spark comes into view in figure I-5 in the later frames of row C, visible at the top of each frame as a dark mottled cloud. The flame progresses downward through the field of view in the frames of rows D to K in the same smooth gradual manner as in figure I-3. In the frames of rows J and K the flame front becomes much more irregular than in the case of figure I-3, but this irregularity is considered to be no greater than is occasionally observed with nonknocking combustion and is not thought to be significant relative to the knock phenomenon. In the frames of row L and the earlier frames of row M the end gas, the area ahead of (below) the flame front, gradually turns dark. By the time of exposure of frame M-10 the end gas has become so dark that it can no longer be distinguished from the combustion zone behind (above) the spark-ignited flame front. This darkening of the end gas, which occurs gradually throughout the frames of row L and the earlier frames of row M, is believed to be indicative of at least the early stages of an autoignition process. In frame M-10, where no line of demarcation can be discerned between the end gas and the burning gases ignited by the normal flame travel, the photographs at least indicate that the end gas is burning just as truly as the gases behind the flame front. The explosive knock reaction that sets up the knocking gas vibrations, however, has not yet begun to develop in frame M-10. The first evidence of this explosive reaction appears in frame M-11 as a white streak along the lower right edge of the frame and as a slight blurring of the dark combustion zone. In the next frame, M-12, the explosive knock reaction has progressed through the entire field of view and has given a fairly uniform white appearance to the entire field. (The whitened area below the lower right edge of frame M-12 is due to a pocket of gas $\frac{1}{16}$ inch thick between the glass window and the metal surface of the cylinder head. This pocket, caused by the window gasket, is completely explained in reference 5.)

At the time of writing of reference 5 the reaction occurring during the exposure of frames M-11 and M-12 was confidently believed to be the explosive knock reaction because the projected motion pictures clearly showed that the gas vibrations began at the same time as the whitening of the field of view in frames M-11 and M-12. Moreover, a violent explosion could be observed in the motion pictures in the general vicinity of the end gas at the same time that this whitening occurred. A more rigid proof that blurring of the combustion zone such as occurs in frame M-11 of figure I-3 coincides chronologically with the onset of violent gas vibrations will be discussed later in this paper. A discussion of the nature of the reaction occurring in frames M-11 and M-12 will also appear later in the paper.

FIGURE I-4.—High-speed photographs of nonknocking combustion in spark-ignition engine with preignition from hot spot. Fuel, S-1; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; spark plug at top; hot spot at bottom; spark timing, 20° B. T. C.

FIGURE I-5.—High-speed photographs of combustion with violent knock in spark-ignition engine. Fuel, 50 percent S-1 with 50 percent M-2; compression ratio, 7.0; fuel-air ratio, about 0.08 atmospheric intake; one spark plug; spark timing, 20° B. T. C.

As previously mentioned, many readers of reference 5 have been entirely unconvinced that the darkening of the end gas prior to the development of the explosive knock reaction in frames M-11 and M-12 ~~actually~~ is autoignition. This author has held the view that this darkening must be regarded as autoignition because there has seemed to be no satisfactory definition of the distinction between preflame and flame reactions in a gradual process occupying a total time interval of less than 1/1000 second (frames L-1 to M-10). In all human experience with flame the preflame reactions have been separated from the flame reactions by a sudden great increase in the rate of reaction, intensity of light radiation, rate of heat release, and so on. The time interval involved in the actual transition from preflame to flame reactions has never been specified and has, in effect, been regarded as instantaneous because of the absence of any method of measuring the interval. The reaction occurring in frames M-11 and M-12 could be regarded as marking the transition from preflame to flame reactions, but so to regard this reaction would be entirely arbitrary and would be only the result of an illogical extrapolation—an extrapolation in the sense that we think because a sharp dividing line appears to exist between preflame and flame reactions when we “see slowly” a sharp dividing line must also be found to exist when we “see fast.”

Qualitatively it could be said that any reaction is proceeding at a very high rate when it produces as much optical change in 1/10,000 second as can be seen between the end gas as it appears in frame M-7 and the end gas as it appears in frame M-10. An investigation is being conducted by G. E. Osterstrom of the NACA technical staff to determine whether the light radiations from the end gas before the explosive knock reaction are sufficient to be measurable. This investigation involves taking simultaneous schlieren photographs and direct flame photographs with a definitely established chronological relationship of the individual frames of one series of photographs to the individual frames of the other series. The preliminary indications are that the radiation from the end gas prior to the explosive knock reaction is sometimes sufficient to photograph at 40,000 frames per second with the high-speed camera. Even if the rate of reaction, intensity of light radiation, and rate of heat release in the end gas could be accurately determined, however, for all of the time intervals covered by frames L-1 to M-10, it would still not be possible to classify the reactions as preflame or flame reactions unless quite arbitrary values were set for these quantities above which the reactions would be regarded as flame reactions.

A possible logical dividing line between preflame and flame reactions on the basis of the thermal theory of autoignition is the condition of more rapid release of heat by the autoigniting gases than normal dissipation of heat from those gases, at constant volume. Another dividing line, based on the chain-reaction theory, is the condition of more rapid formation of chain carriers by chain-branching reactions than destruction of carriers by chain-breaking reactions. Measurements indicate that the normal flame

front did not make any additional progress into the end gas between frames M-1 and M-10 of figure I-5. Furthermore, many photographs have been obtained in which the normal flame front as seen in the projected photographs was actually pushed backward by the end gas a number of frames prior to the development of the explosive knock reaction. Because of this fact, the dividing line on the basis of thermal theory must have been passed at about frame M-1 in figure I-5, so that the end-gas reaction between frames M-1 and M-10 would have to be regarded as flame reaction, unless it is assumed that the end gas is being heated by radiation and conduction from the burning gases more rapidly than the average of the other gases in the chamber including the burning gases themselves. There is no indication, of course, as to where the dividing line based on chain-reaction theory would be drawn relative to the frames of figure I-5.

In view of the necessarily arbitrary nature of any distinction between preflame and flame reactions in frames L-1 to M-10 of figure I-5, the fact that the end gas does sometimes emit sufficient light to photograph by direct flame photography at 40,000 frames per second prior to the explosive knock reaction, and the fact that preknock radiations from the end gas have been photographed at a lower speed by other investigators (reference 46), the reaction visible in the end gas throughout frames L-1 to M-10 of figure I-5 and similar reactions visible in other figures will be referred to throughout this paper as simply “autoignition.” The reaction of frames M-11 and M-12 will be shown later to be a detonation wave and may be regarded as autoignition only in the sense that it develops during a process of autoignition and that its development may be influenced by the autoignition process.

The frames following M-12 in figure I-5 show the development of an extremely brilliant, intermittent luminosity reaching peaks in frames M-16, N-1, N-6, O-1, and so on, and the development of an intense smoke cloud in the lower parts of the frames of rows P, Q, and R. The brilliant luminosity and smoke formation will be discussed further under “Chemical Nature of Explosive Knock Reaction.” The extremely violent vibration, or bouncing, of the gases that is seen when frames M-12 to R-18 are projected on the screen as a motion picture cannot be seen in visual examination of the photographs in the printed figures. This effect is suggestive of a pot of stiff jelly that has been severely jolted and is characteristic of all of the photographs of knocking combustion obtained with the high-speed camera.

Chronological relation between schlieren photographs and records of cylinder pressure.—In the photographs of figure I-5 the occurrence of knock is very definitely visible in frames M-11 and M-12. In cases of much lighter knocks, however, the occurrence of the knock may be detected in the photographs only as a slight blurring of the dark mottled combustion zone. This blurring is often not visible in the printed reproductions of the photographs, because of inevitable loss of detail, but can be seen on careful inspection of

the original negatives. Inasmuch as the slight blurring of the combustion zone could not be assumed without proof to be identical with the occurrence of knock, one of the early investigations (reference 7) was directed toward the establishment of a definite chronological relationship between this blur and the beginning of the violent gas vibrations associated with knock. Incidental to this relation, some investigation was also made into the chronological relation between the final fadeout of the schlieren combustion pattern and the attainment of peak pressure with nonknocking combustion.

One of the high-speed photographic shots used in the establishment of the chronological relationship is reproduced as figure I-6 of this paper (fig. 11 of reference 7). Three spark plugs were used, in E, F, and G positions (see fig. I-1), a quartz piezoelectric pickup was used in opening J, and the injection valve was in opening H. The spark timing at the plugs in E and F positions was 22° B. T. C. The timing at the plug in G position was earlier (29° B. T. C.) because it was desired to focus the end zone at the diaphragm of the piezoelectric pickup in opening J, and to do so required a

FIGURE I-6.—High-speed photographs of knocking combustion in spark-ignition engine with timing sparks in row A. Fuel, 80 percent S-1 with 20 percent M-2; compression ratio, 7.4; fuel, air ratio, about 0.08; atmospheric intake; three spark plugs; spark timing, for left-hand plug, 29° B. T. C., for other two plugs, 22° B. T. C.; B, blurring caused by knock.

much longer travel for the flame from G position than for the flames from E and F positions. The fuel was a blend of 80 percent S-1 and 20 percent M-2 reference fuels; compression ratio 7.4; and fuel-air ratio, approximately 0.08.

The flames from the three igniting sparks come into view in the frames of rows A to E of figure I-6. By the frames of row I the flames have completely merged and have surrounded a small body of end gas in the immediate vicinity of the piezoelectric pickup diaphragm. In the first nine frames of row J autoignition takes place in the end gas, and in frame J-10 knock occurs, as indicated by the blurring and lightening of the combustion zone in the region designated B.

In row A the film perforations are included in the figure. (The perforations were trimmed from the reproductions used for the other rows.) In the taking of the pictures the film was placed around the inside of a drum in a continuous circle consisting of 372 frames. Of the 372 frames, 168 are omitted from the figure after frame J-18 (or before frame A-1 and 28 are omitted as indicated in row A. A specially designed spark plug in the camera produced a timing mark in the perforation strip at frame A-10 at about the time of the beginning of combustion. The same spark plug produced another timing mark at frame A-2, 339½ frames later, after the combustion and knock were completed. These two timing sparks have been used in the determination of the chronological relationship between the photographs of figure I-6 and the corresponding pressure record of figure I-7.

In figure I-7 the trace designated A is an actual photograph of a trace produced on the screen of a cathode-ray oscilloscope during the exposure of the photographs of figure I-6. The horizontal plates were used, as usual, to produce a time sweep. Two independent voltages were applied to the vertical-plate circuit: a small alternating voltage produced by a 4000-cycle-per-second oscillator, and the voltage produced by the piezoelectric pickup in opening J of the cylinder head. The trace designated B in figure I-7 is an actual photograph of the trace produced on another cathode-ray oscilloscope screen during the exposure of the photographs of figure I-6. In the case of trace B, however, only the voltage from the 4000-cycle-per-second oscillator was applied to the vertical-plate circuit.

The electric conduit that supplied the sparking voltages to the spark plug in the camera was coupled capacitatively with the vertical deflection-plate circuits of both oscilloscopes. This coupling produced the breaks designated F in the two oscillograph traces at the time of the first timing spark (see frame A-10 of fig. I-6) and the breaks designated J at the time of the second timing spark (frame A-2 of fig. I-6). The break designated K in figure I-7 was caused by the first shock on the diaphragm of the piezoelectric pickup at the time of beginning of the gas vibrations in the combustion chamber.

The point in the high-speed camera at which the timing marks were produced and the point in the camera at which

the end gas was photographed are separated by a distance of approximately 34½ frames. Because of this separation, necessitated by mechanical considerations, the breaks F in the oscillograph traces of figure I-7 occurred 196½ (not 162) frames before the development of the knocking blur at B in frame J-10 of figure I-6. Likewise, the breaks J in figure I-7 occurred 143 (not 177½) frames after the development of the knocking blur. In trace B of figure I-7, between breaks F and J, 32.8 oscillator cycles were counted (reference 7); there were therefore $\frac{339.5}{32.8}$ or 10.35 motion-picture frames per oscillator cycle. (The second oscilloscope was provided solely because in many cases the disturbances in trace A caused by the knocking gas vibrations were so violent that it was not possible to count oscillator cycles between breaks F and J in trace A.) Nineteen oscillator cycles were counted (reference 7) on trace A of figure I-7 between the break F and the break K; the knocking break K therefore occurred approximately 196½ frames after the first timing spark. This value agrees exactly with the 196½ frames that separated

FIGURE I-7.—Composite pressure-time and oscillator trace A and separate oscillator trace B for combustion process of figure I-6. F, breaks caused by first timing spark (frame A-10 of fig. I-6); J, breaks caused by second timing spark (frame A-2 of fig. I-6); K, break caused by start of knock (frame J-10 of fig. I-6); piezoelectric pickup in opening J. (See fig. I-1.)

the first timing spark chronologically from the knocking blur in frame J-10 of figure I-6. (The picture-taking rate is known from camera-acceleration data to be constant within a very small fraction of 1 percent over the period of time involved in the determination, and the frequency of the oscillator output is believed to be similarly constant over the very short time interval involved.)

In eight cases with the end zone in contact with the diaphragm of the piezoelectric pickup the knocking blur was found, by the method used with figures I-6 and I-7, to coincide chronologically with the start of the violent gas vibrations within one-half motion-picture frame. In 16 cases where the end gas was on the opposite side of the chamber from the piezoelectric pickup, the same method indicated that the knocking blur preceded the start of the violent gas vibrations by $4 \pm 1\frac{1}{2}$ motion-picture frames, the value of four motion-picture frames being accounted for by the time required for the knocking disturbance to travel at the speed of sound from the end gas to the diaphragm of the piezoelectric pickup.

FIGURE I-8.—High-speed photographs of nonknocking combustion in spark-ignition engine with timing sparks in rows D and J. Fuel, S-1; compression ratio, 7.4; fuel-air ratio, about 0.08; atmospheric intake; four spark plugs; spark timing, for left-hand plug, 29° B. T. C., for other three plugs, 22° B. T. C. Frames 1 to 19 selected as point of final fadeout of schlieren pattern.

FIGURE I-9.—Pressure-time record A for nonknocking combustion process of figure 8 and separate oscillator trace B. E and G, breaks caused by ignition sparks; F, break caused by first timing spark (frame J-18 of fig. I-8); J, break caused by second timing spark (frame D-12 of fig. I-8); H, point of peak pressure; piezoelectric pickup in opening I. (See fig. I-1.)

A somewhat similar but less accurate method of determining the chronological relationship is illustrated by figures I-8 and I-9 (same as figs. 15 and 16 of reference 7) as applied to the significance of the mottled combustion pattern in the schlieren pictures. Figure I-8 is a shot of normal nonknocking combustion. Engine operating conditions were the same as with the combustion of figure I-6 except that the piezoelectric pickup was placed in opening I (see fig. I-1) and an additional spark plug replaced the piezoelectric pickup at opening J. The fuel was S-1 reference fuel. Ninety-five frames were omitted from figure I-8 after frame J-22 (or before frame A-1), 3 frames were lost at the splice at frame J-2, and 61 frames were omitted as indicated in row J. The first timing spark was exposed before the camera began taking pictures, at frame J-18, and the second timing spark

was exposed 549 frames later, after the camera had ceased taking pictures, at frame D-12.

The first and second timing sparks caused the breaks F and J, respectively, in the pressure-time trace A in figure I-9. With this method the 4000-cycle-per-second oscillator record was not superposed on the pressure-time record. Only one oscilloscope was used. After the pressure-time record was exposed, simultaneously with the exposure of the high-speed photographs, the piezoelectric pickup was immediately disconnected from the vertical-plate circuit of the oscilloscope, the 4000-cycle-per-second oscillator was connected to the vertical-plate circuit, and a second time sweep of the oscilloscope beam was produced, giving the trace B in figure I-9. The trace B was used solely as a measure of the nonlinearity of the time sweep of the oscilloscope. Lines corresponding to constant voltage on the horizontal deflection plates were drawn through trace B from breaks F and J in trace A and also from the point H in trace A, which was considered to be the point of maximum pressure, as shown by trace A. By simple proportionality, the point H in trace A of figure I-9 was found to coincide chronologically with the exposure of frame J-4 of figure I-8 (with due allowance for the $34\frac{1}{2}$ frame correction previously mentioned). Upon careful examination of the original negatives of figure I-8, frame I-19 was selected as the point of final fadeout of the

mottled combustion zone; the difference between times of exposure of frames I-19 and J-4 is 250 microseconds, or only 0.75° of crankshaft rotation.

In five cases similar to that of figures I-8 and I-9 the final fadeout of the schlieren combustion pattern in the photographs was found to precede peak pressure by $0.3 \pm 0.7^\circ$ of crankshaft rotation. As explained in reference 7, peak pressure and the fadeout of the schlieren combustion pattern were so close to top center that no correction was required for piston motion. In 47 cases where the method of figures I-8 and I-9 was applied to knocking combustion, with the end zone on the opposite side of the chamber from the piezoelectric pickup, the knocking blur was found to precede the start of the violent gas vibrations by 8 ± 6 motion-picture frames, as compared with $4 \pm 1\frac{1}{2}$ motion-picture frames in the 16 cases in which the method of figures I-6 and I-7 was used. The method of figures I-8 and I-9 is inherently less accurate than that of figures I-6 and I-7, the principal sources of error probably being lack of reproducibility of the time sweep of the oscilloscope and some slight interaction between the vertical- and horizontal-plate circuits of the oscilloscope. The comparison of the two methods indicates that the method of figures I-8 and I-9 is reproducible within $\pm 0.5^\circ$ of crankshaft rotation and that it has a constant error of about 0.6° of crankshaft rotation. Applying the indi-

FIGURE I-10.—High-speed photographs of homogeneous end-gas autoignition preceding knock in spark-ignition engine. Fuel, M-2; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; four spark plugs; spark timing, for left-hand plug, 27° B. T. C., for other three plugs, 20° B. T. C.; A, regions where burning is complete; B, blurring caused by knock.

FIGURE I-11.—High-speed photographs of homogeneous autoignition throughout large volume of end gas before knock in spark-ignition engine. Fuel, M-4; compression ratio, 8.7; fuel-air ratio, about 0.17; inlet-air temperature, 445° F; inlet-air pressure, atmospheric; four spark plugs; spark timing, 20° B. T. C.

cated correction for the constant error results in the finding that peak pressure preceded the final fadeout of the mottled combustion zone by $0.3 \pm 0.7^\circ$ of crankshaft rotation. The 0.7° variation from the mean is almost within the demonstrated inaccuracy of the method. It is doubtful whether the point of peak pressure could be selected more accurately than within 0.3° of crankshaft rotation in traces like that of figure I-9.

From the investigation summarized here (reference 7) two conclusions appear justified: first, that the characteristic knocking blur seen in the high-speed photographs does represent the reaction that sets up the violent gas vibrations associated with knock and, second, that the mottled combustion zone does represent continuing combustion, at least so far as the termination of combustion is concerned. The second conclusion as applied to combustion in a constant-volume bomb was previously reached by Lindner (reference 65).

Six types of end-gas autoignition.—The high-speed photographs have revealed six different types of autoignition in the end gas. Some of these types may be interrelated; others seem to be quite distinct. The type of autoignition that will occur under conditions sufficiently severe appears to depend largely upon the fuel used, although the scope of

the investigations has not been sufficient to rule out all other factors entirely as affecting the type of autoignition that will occur. Some other types of autoignition have been followed by the explosive knock reaction in all of the NACA tests where they occurred; other types have been followed by the explosive knock reaction in some cases, in other cases not.

The homogeneous type of autoignition (occurring simultaneously and uniformly throughout the entire body of end gas) is observed in frames L-1 to M-10 of figure I-5 and in frames J-1 to J-9 of figure I-6. This type of autoignition is also well shown in frames G-1 to G-11 of figure I-10, a reproduction of figure 7 of reference 6. (Four spark plugs were used for the combustion process of fig. I-10. The injection valve was in position H of fig. I-1. The fuel was M-2 reference fuel, the spark timing 20° B. T. C. for the plugs in E, F, and J positions and 27° B. T. C. for the plug in G position, compression ratio 7.0, and fuel-air ratio approximately 0.08.) The explosive knock reaction occurs in the area designated B in frame G-12 of figure I-10. The white regions designated A in frame G-10 of the figure are the regions in which combustion is complete; they should not be confused with the end zone which is visible as a white area in frame G-1 but which has become completely dark in frame G-10.

Practically homogeneous autoignition is seen in figure I-11 throughout an end zone very much larger than the end zones of figures I-5, I-6, and I-10. The full-view combustion apparatus was used for the photographs of figure I-11. These photographs were obtained in a recent investigation conducted by H. L. Olsen of the NACA technical staff, as were all photographs of combustion in the full-view apparatus presented later in this paper. Four spark plugs were used in the combustion process for this figure; the flames from three of the plugs made considerable progress through the gases before the first frame of the series was taken, whereas the flame from the fourth spark plug develops very slowly throughout the frames of rows A to D of the figure. The positions of the four spark plugs are shown as B, C, E, and F at frame A-1 of the figure, corresponding to the same lettered positions in figure I-2. The injection valve was in position A (see fig. I-2); the fuel was M-4 reference fuel; spark timing, 20° B. T. C.; compression ratio, approximately 8.7; fuel-air ratio, about 0.17; inlet-air temperature, 445° F; and inlet-air pressure, atmospheric. (Fuel-air ratio was adjusted approximately to maximum knock value; the abnormally high value of 0.17 was required probably because of incomplete fuel vaporization obtained with injection on the compression stroke.)

More than half the total volume of the combustion chamber is involved in the autoignition that developed in the case of figure I-11. The autoignition is first visible as a wisp of mottled gas indicated by the arrow in frame C-1. In all the frames of rows C and D mottling appears throughout the entire area of the end gas, and between frames E-1 and E-7 the entire end gas becomes very dark. The first evidence of the explosive knock reaction appears in frame E-8 and the combustion is completed by frame F-4. The knock in this case was extremely heavy. The pressure-time trace from reference 12 (not reproduced in this paper) indicated a very considerable pressure rise caused by the homogeneous autoignition before the development of the explosive knock reaction.

Homogeneous autoignition has always been followed by the explosive knock reaction in the NACA tests.* In some cases, however, the knock has been quite light in spite of a very large homogeneously igniting end zone, and cases will be presented in which heavy knock has developed in the burning gases alongside of a large end-zone area in which no autoignition has taken place.

A second type of end-gas autoignition, which might be termed "pinpoint" autoignition, is shown in figures I-12 to I-15. Figure I-12 is reproduced from reference 9. In the

FIGURE I-12.—High-speed photographs of pinpoint end-gas autoignition preceding knock in spark-ignition engine. Fuel, S-1 with 200 ml amyl nitrate per gallon; compression ratio, 7.1; fuel-air ratio, about 0.08; atmospheric intake; two spark plugs; spark timing, at G position (fig. I-1); 27° B. T. C., at F position, 20° B. T. C.; B, luminosity caused by knock.

*Since the writing of this paper a photograph has been obtained by G. E. Osterstrom, NACA, with *n*-heptane fuel, showing homogeneous autoignition throughout a third of the combustion-chamber volume without any evidence of the explosive knock reaction either in the photographs or in the pressure-time record.

FIGURE I-13.—High-speed photographs of pinpoint end-gas autoignition without knock in spark-ignition engine. Fuel, benzene; compression ratio, 9.0; inlet-air temperature, 425° F; inlet-air pressure, atmospheric; four spark plugs; spark timing, 21° B. T. C.

FIGURE I-14.—High-speed photographs of pinpoint end-gas autoignition followed by very light knock in spark-ignition engine. Fuel, triptane; compression ratio, 9.0; fuel-air ratio, about 0.22; inlet-air temperature, 312° F; inlet-air pressure, 20 pounds per square inch; four spark plugs; spark timing, 18° B. T. C.

FIGURE I-15.—High-speed photographs of pinpoint end-gas autoignition followed by violent knock in spark-ignition engine. Fuel, S-4; compression ratio, 9.0; fuel-air ratio, about 0.25; inlet-air temperature, 446° F; inlet-air pressure, 18.5 pounds per square inch absolute; four spark plugs; spark timing, 18° B. T. C.

case of figure I-12, taken with the old combustion apparatus, only two spark plugs fired. The spark plug in G position (see fig. I-1) was timed at 27° B. T. C.; that in F position at 20° B. T. C. The injection valve was in H position. The fuel was S-1 reference fuel with admixture of 200 ml amyl nitrate per gallon. The compression ratio was 7.1 and the fuel-air ratio approximately 0.08. The dark frames, D-5 to D-16, in figure I-12 should be disregarded; their appearance was caused by faulty processing of film. The pinpoint autoignition begins to develop in the later frames of row F as very small black dots distributed throughout the end gas. Throughout frames G-1 to G-10 these black dots gradually grow larger until they completely fill the end zone. The explosive knock reaction is first visible at B in frame G-11 and has spread throughout the entire visible part of the chamber in frame G-12. The knock in this case appears to have been violent.

The combustion processes of figures I-13, I-14, and I-15 were fired in the full-view combustion apparatus with four spark plugs timed at 21°, 18°, and 18° B. T. C., respectively. In each case the injection valve was in position A (fig. I-2) and the compression ratio in each case was 9.0. The inlet-air temperatures were 425°, 312°, and 446° F, and the absolute inlet-air pressures atmospheric, 20, and 18.5 pounds per square inch, respectively. The fuel-air ratios for figures I-14 and I-15 were about 0.22 and 0.25, respectively. The

fuel-air ratio for the case of figure I-13 is not known even to an approximation, but it is thought not to be greatly different from the values for the other figures because the flame speeds are of the same order. The fuels for the three cases were benzene, triptane, and S-4 reference fuel, respectively. In each of these three cases the pinpoint autoignition is clearly visible in the end gas (rows D and E of fig. I-13, rows B, C, and D of fig. I-14, and rows B to E of fig. I-15). In many cases the first visibility of the pinpoints is indicated by a small arrow. Careful measurements show that each pinpoint grows at the rate that should be expected if the flame spread out in all directions from a point origin at the same speed as that of the normal flames traveling from the igniting sparks. In the case of benzene (fig. I-13) the pinpoint autoignition does not result in even the slightest gas vibrations. The projected motion pictures appear smooth throughout the entire process. The combustion zone fades out very gradually throughout the frames of rows F, G, and H; this very gradual fadeout is typical of nonknocking combustion and is never seen after occurrence of an explosive knock reaction of any appreciable violence. The pressure-time record (fig. I-16 (a)) shows not the slightest evidence of gas vibration. (All the pressure-time traces of fig. I-16 were obtained from a piezoelectric pickup in position D, fig. I-2.) In the case of triptane (fig. I-14) the development of the pinpoint autoignition and the gradual fadeout

(a) Indicator card for combustion process of figure I-13, showing hot-gas vibrations.
 (b) Indicator card for combustion process of figure I-14, showing light gas vibrations.
 (c) Indicator card for combustion process of figure I-15, showing extremely violent gas vibrations.

Figure I-16.—Pressure-time records.

of the combustion zone is quite similar to the benzene case except that an extremely light knock develops at about frame G-6. The knock at frame G-6 cannot be detected by visual examination of the figure but is seen when the photographs are projected as a motion picture. Also the pressure-time record (fig. I-16 (b)) shows very light gas vibrations starting at the point of peak pressure. In the case of S-4 reference fuel (fig. I-15) the pinpoint autoignition develops in frames B-11 to E-8 and a violent explosive knock reaction develops in frames E-9 and E-10. Upon careful examination unignited end-gas areas may still be seen in frames E-8 and E-9. Some of these unignited end-gas areas still appear white in frame E-10; it appears if the gas in these regions ever burned it did so in a very short interval relative to the photographic exposure time of 25 microseconds. The pressure-time record for the case of S-4 reference fuel (fig. I-16 (c)) shows very violent knock occurring at a time when the heat release from the normal combustion was still rapid.

Figures I-12 to I-16 do not indicate that pinpoint autoignition is in any way related to the explosive knock reaction; this type of autoignition may occur with or without the explosive knock reaction and, as shown by the previous figures, the explosive knock reaction may occur without pinpoint autoignition.

A third type of end-gas autoignition, perhaps fundamentally identical with homogeneous autoignition, is the two-stage type seen in figure I-17. This combustion process was

FIGURE I-17.—High-speed photographs of two-stage end-gas autoignition followed by heavy knock in spark-ignition engine. Fuel, M-4; compression ratio, 7.0; inlet air temperature, 398° F; inlet-air pressure, atmospheric; four spark plugs; spark timing, 21° B. T. C.

fired in the full-view combustion apparatus with four spark plugs timed at 21° B. T. C. The injection valve was in position A (fig. I-2); the fuel was M-4 reference fuel; compression ratio, 7.0; inlet-air temperature, 398° F; and inlet-air pressure, atmospheric. The fuel-air ratio is not known but is believed to be quite lean—near the lower limit of flammability. The spark plug at F position (frame A-1) apparently did not fire. The flame from C position is quite indistinct in the frames of rows A and B, but becomes quite sharply defined in rows C and D. The flames from B and E positions are sharply defined throughout rows A to D. The indistinct appearance of the flame from C position in the first two rows of the figure may be an indication that this flame is a borderline case between autoignition and normal propagated flame. A definite case of this type will be presented later in this

section. At about frame D-6 in figure I-17 definite autoignition begins to develop as a wisp of mottled gas, indicated by the arrow in this frame. The wisp indicated in frame D-6 serves as a boundary line in the following frames between homogeneously autoigniting gases and nonautoigniting gases. The gases to the right of this wisp autoignite in frames D-7 to E-5. The gases to the left of the wisp show no evidence whatever of autoignition between the frames D-7 and E-5. The gases to the left of the wisp do autoignite, however, in frames E-6 to E-8. The beginning of a violent explosive knock reaction is apparent in frame E-9.

FIGURE I-18.—High-speed photographs of runaway flame preceding violent knock in spark-ignition engine. Fuel, M-4; compression ratio, 9.0; fuel-air ratio, about 0.17; inlet-air temperature, 415° F; inlet-air pressure, 15.5 pounds per square inch absolute; four spark plugs; spark timing, 20° B. T. C.

A fourth type of end-gas autoignition appears in figure I-18 as a wild runaway flame. Because of an accident the photographs of this figure were taken under uniquely severe conditions for the fuel used. No attempt was made to

ratio was 9.0; fuel-air ratio, about 0.17; inlet-air temperature, 415° F; and absolute inlet-air pressure, 15.5 pounds per square inch.

Because of the very severe conditions the charge was apparently ready to autoignite at the time the camera shutter opened for the photographs of figure I-18. The entire combustion process, including the explosive knock reaction, took place within 16 motion-picture frames after the camera shutter started to open. For this reason, the frames do not become well illuminated until about the middle of row B, at which time the camera shutter was open sufficiently to produce fair pictures. The spark-plug positions are indicated at frame A-1. At frame A-7 the flames from B and F positions are fairly visible. The flames from C and E positions cannot be seen in the printed reproduction of

FIGURE I-19. High-speed photographs of development of preknock autoignition flame at far wall of chamber in spark-ignition engine. Fuel, S-2 with 400 ml amyl nitrate per gallon; compression ratio, 7.1; fuel-air ratio, about 0.08; atmospheric intake; one spark plug; spark timing, 20° B. T. C.

FIGURE I-20.—High-speed photographs of vibratory combustion preceding knock in spark-ignition engine. Fuel, M-2 with 200 ml TEL per gallon; compression ratio, 7.1; fuel-air ratio, about 0.08; atmospheric intake; four spark-plugs; spark timing, for left-hand plug, 27° B. T. C., for other three plugs, 20° B. T. C.; B, blurring caused by knock.

frame A-7, but both of these flames can be seen on careful inspection of the original negative. At frame B-1 the flame from B position breaks loose and it travels all the way across the chamber in frames B-1 to C-1 at a speed of 1900 feet per second. The explosive knock reaction occurs after this flame has completed its travel across the chamber at frame C-2, as shown by the sudden whitening of the entire chamber. In frame B-7, after the runaway flame has nearly completed its travel across the chamber, the flame from E position may be clearly seen still apparently under complete control.

When the photographs of figure I-18 are projected as a motion picture the phenomenon seen in row B of the figure has every appearance of a very fast propagated flame. On close inspection of the still photographs, however, it is found that the leading edge of this flame is never sharply defined and the phenomenon appears to be in fact a multistage autoignition process, similar to the phenomenon of figure I-17 but occurring in many more than two stages. This phenomenon is regarded as a borderline case between homogeneous autoignition and a detonation wave. The occurrence of the explosive knock reaction at frame C-2 of the figure will be further discussed in a later section.

A fifth type of end-gas autoignition is shown in figure I-19, same as figure 13 of reference 9. This combustion process

was fired in the old combustion apparatus with one spark plug in E position (fig. I-1) timed at 20° B. T. C. The injection valve was in H position, the fuel was S-2 admixed with 400 ml amyl nitrate per gallon, compression ratio 7.1, and fuel-air ratio about 0.08. In this case the autoignition occurred as a flame developing at the far wall of the chamber and propagating out from the wall to meet the spark-ignited flame. A slight mottling near the far wall of the chamber (lower edge of the chamber as seen in the photographs) develops in the frames of row K of the figure. Also, in the later frames of row K, a few centers of pinpoint autoignition develop near the far wall of the chamber. In the frames of row L additional pinpoints of autoignition develop and a definite flame propagation begins to proceed out from the far wall. This orderly autoignition-flame propagation proceeds throughout the entire end gas in the frames of row M, and in the frames of row N the mottled combustion zone gradually fades out. When the photographs are observed as motion pictures only a very light explosive knock reaction is seen in the frames of row N; this reaction is so light that it cannot be identified as being associated with any particular motion-picture frame. The type of autoignition shown in figure I-19 may be a special case of pinpoint autoignition.

The sixth type of autoignition, an example of which

FIGURE I-21.—Apparent flame-front velocities during period of preknock vibration in spark ignition engine.

occurred in the combustion process of figure I-20, is detectable only through the slight preknock vibration which it imparts to the gases. Figure I-20 is a reproduction of figure 2 of reference 9. For this combustion process four spark plugs were used, timed at 20° B. T. C. in E, F, and J positions (fig. I-1) and at 27° B. T. C. in G position. The injection valve was in H position, the compression ratio was 7.1, and the fuel-air ratio about 0.08. The fuel was M-2 reference fuel with an extremely high concentration of tetraethyl lead—200 ml per gallon. Some pinpoint autoignition may be seen in the photographs, originating at centers indicated by the arrows at frames F-10 and F-14. No other visual evidence of autoignition appears, however, and when the explosive knock reaction begins at B in frame G-7 some apparently unignited end gas is still visible at the lower right corner of the chamber. In the original work (reference 9) flame areas were measured on greatly enlarged copies of the individual frames of the figure with a polar planimeter. The results showed that the end gas suddenly expanded at

about frame E-1 of figure I-20, and that between frames E-1 and G-7 at least three cycles of vibration of the gases occurred. The measurements indicated that the amplitude of the vibrations did not increase (in fact, usually diminished)

FIGURE I-22.—Actual pressure-time records showing increase in number of cycles of preknock vibration with increasing tetraethyl lead concentration in fuel.

after the first cycle, from which fact it was concluded that a mild explosive reaction occurred in the end gas at about frame E-1. When the photographs of figure I-20 are projected as a motion picture, four cycles of vibration of the gases are easily observed before the explosive knock reaction at frame G-7; they are observed as a backward and forward motion of the flame fronts.

Figure I-21 shows the preknock vibration determined from planimeter measurements of flame areas for different concentrations of tetraethyl lead. A similar variation in number of cycles of preknock vibration with varying tetraethyl lead concentration is shown by the actual pressure-time records of figure I-22, obtained with a piezoelectric pickup in opening I of the cylinder head (fig. I-1). The time interval involved in the preknock vibration was found to increase linearly with the tetraethyl lead concentration up to 200 ml per gallon, the highest concentration used.

Explosive knock reaction without end-gas autoignition.—Many high-speed photographs have been obtained like the ones of figure I-23, in which the end gas appeared to be entirely consumed by the normal flames some time before the occurrence of the explosive knock reaction. This figure is a reproduction of figure 6 of reference 6. Four spark

plugs were used for this combustion, timed at 20° B. T. C. at E, F, and J positions (fig. I-1) and at 27° B. T. C. at G position. The injection valve was at position H, the fuel was a blend of 50 percent 95-octane gasoline with 50 percent M-2 reference fuel, compression ratio 7.0, and fuel-air ratio about 0.08. The last visible end gas disappears, because of normal flame travel, at about frame G-17. The explosive knock reaction occurs at B in frame H-7, 11 frames after the disappearance of the last visible end gas. Other photographs have been obtained in which a mild explosive knock reaction occurred not only after the disappearance of the last visible end gas but even after the entire schlieren combustion pattern had almost faded out (reference 6).

The cases cited are not good proof that the explosive knock reaction can occur without autoignition because of the possible existence of unignited gas pockets in front of or behind the burning gases; such pockets could, of course, not be seen in the photographs. Photographs have been obtained, however, in which unignited end gas may actually be seen at the time the explosive knock reaction occurs and the unignited end gas does not appear to play a part in the explosive knock reaction. Comment has already been made concerning the presence of unignited end gas in one part of

FIGURE I-23.—High-speed photographs showing apparent complete merging of flames before knock in spark-ignition engine. Fuel, 50 percent 95-octane gasoline with 50 percent M-2; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; four spark plugs; spark timing, for left-hand plug, 27° B. T. C., for other three plugs, 20° B. T. C.; A, completely burned regions; B, blurring caused by knock.

FIGURE I-24.—High-speed photographs of occurrence of violent knock in spark-ignition engine while unignited end gas is still visible. Fuel, S-4; compression ratio, 9.0; fuel-air ratio, about 0.13; inlet-air temperature, 310° F; inlet-air pressure, 15.5 pounds per square inch absolute; four spark plugs; spark timing, 18° B. T. C.

frame G-7 of figure I-20 at the same time that the explosive knock reaction begins in another part of the same frame. A more striking example of this phenomenon appears in figure I-24. Four spark plugs were used in the case of figure I-24, timed at 18° B. T. C. The injection valve was in position A (fig. I-2); the fuel was S-4 reference fuel; compression ratio, 9.0; fuel-air ratio, about 0.13; inlet-air temperature, 310° F; and absolute inlet-air pressure, 15.5 pounds per square inch. In frame F-2 of this figure a fair-sized white unignited end zone is visible, slightly below the center of the chamber, roughly in the shape of a T lying on its side. The explosive knock reaction begins in frame F-3, as indicated by the blurring of the dark mottled combustion zone. This dark mottled combustion zone encroaches somewhat upon the unignited end gas in frame F-3, but most of the end gas visible in frame F-2 remains unignited in frame F-3 in spite of the effect of the explosive knock reaction on the actual combustion zone in frame F-3. Moreover, the end gas that appears white and unignited in frame F-3 still appears white in frames F-4 and F-5, in which the explosive knock reaction is completed. If this body of end gas ever did burn it must have done so in a time interval much shorter than the 25-microsecond exposure time of the individual frames of the figure, or it would have

shown the characteristic dark mottled appearance of burning gas in one of the frames of the figure.

The appearance of frames F-2 to F-5 of figure I-24 indicates that the explosive knock reaction developed in the dark mottled combustion zone and that its effect on the unignited end gas, if it had any such effect, was only incidental. In reference 7 it was concluded that the explosive knock reaction develops only in gases that have been previously ignited either by normal flame travel or by auto-ignition. Photographs were presented in the same paper indicating that the origin of the explosive knock reaction was not necessarily in the same location as the last gas to be ignited.

Physical nature of explosive knock reaction as indicated by high-speed photographs.—From a study of photographs taken at 40,000 frames per second the author of this paper has concluded (reference 10) that the explosive knock reaction is a type of detonation wave traveling through the unburned, or incompletely burned, gases at a speed ranging approximately from one to two times the speed of sound in the burned gases. An example of a detonation wave moving at a speed twice that of sound in the burned gases is found in frames M-11 and M-12 of figure I-5. As previously noted, the explosive knock reaction in this case is first visible as a white streak along the lower right edge of frame M-11

and as a slight blurring of the combustion zone in the same frame. The next frame, M-12, has been rendered white throughout by the knock reaction. As explained in reference 10, it is believed justifiable to disregard the blurring of the mottled combustion zone in frame M-11 and to use the appearances of brilliant luminosity as a measure of the speed of the knock disturbance. On such a basis, the superficial impression obtained from frames M-11 and M-12 of figure I-5 is that the knock disturbance started at the lower right edge of the chamber and spread very rapidly throughout the charge from the point of origin. When the photographs are analyzed, however, with proper allowance for the focal-plane-shutter effect of the camera (reference 1), it is found that the travel of the knock disturbance as shown by frames

tive to the combustion-chamber image as the leading edge of the focal-plane-shutter slit of the camera exposing frame M-12.

Figures I-25 and I-26 are reproductions of portions of a motion-picture animation (reference 12) created for the purpose of demonstrating the manner of exposure of frames M-11 and M-12 of figure I-5. Figure I-25 shows this author's conception of what actually happened during the exposure of the two frames. In this figure the focal-plane shutter is assumed to have been removed from each of the still cameras. The frames of the figure show what would have been seen on the film in each of the two cameras if the film and the image appearing upon it could have been photographed at the rate of about 180,000 frames per second.

FIGURE I-25.—Animation showing detonation-wave travel as it might appear on film in two still cameras if film and image were photographed at about 180,000 frames per second. Development of detonation wave in frames B-2 to B-8 of this figure corresponds chronologically with exposure of frames M-11 and M-12 of figure I-5.

M-11 and M-12 was actually in a direction opposite to the superficially apparent direction.

An optical effect equivalent to that of the high-speed camera would be obtained if frames M-11 and M-12 of figure I-5 were exposed by two independent still cameras using focal-plane shutters, provided the following three conditions were satisfied: first, the width of the slit aperture in each of the focal-plane shutters must be equal to half the frame spacing, or about $7/10$ the width (not the length) of the combustion chamber as seen in the photographs, second, each focal-plane-shutter slit must travel a distance equal to its own width in $1/40,000$ second in a direction from left to right, as seen in figure I-5 (that is, in the direction away from the previously exposed frames toward the frames yet to be exposed as seen in the figure), and third, the trailing edge of the focal-plane-shutter slit of the camera exposing frame M-11 must at all times be in the same position rela-

The frames are arranged in three rows of eight frames each. Each frame includes two images of the combustion chamber; the lower of the two images is the one seen on the film in the camera exposing frame M-11, the upper of the two images is the one seen on the film in the camera exposing frame M-12. Inasmuch as the focal-plane shutters have been removed from the cameras, and the cameras are still cameras of the most elementary type, the same image appears on the film in both cameras at all times. Throughout the frames of row A and the first frame of row B the film in each camera is being exposed to an image just like that of frame M-10 (fig. I-5). At frame B-2 (fig. I-25) a detonation wave originates at the lower left corner of the visible portion of the chamber as indicated by the two white arrows in this frame. This wave travels across the chamber through the dark mottled combustion zone as seen on the film in each of the two cameras between frames B-2 and B-8. (The

detonation-wave front has been made straight for simplicity of construction of the animation; approximately the same effect would have resulted if the detonation-wave front had been spherical.) The gases behind the detonation-wave front are, of course, incandescent and the entire area that was formerly the dark mottled combustion zone consequently appears brilliant white in all of the frames after the detonation-wave front has completed its travel (frames B-8 to C-8).

Figure I-26 is an animation of the same kind as figure I-25 but shows the motion of the focal-plane shutter in each of the two cameras as well as the progress of the detonation wave. In frame A-1 of figure I-26 the focal-plane-shutter slit that will provide the exposure for the lower photograph (frame M-11 of fig. I-5) may be seen just to the left of the combustion-chamber image as a tall narrow rectangle. Part of the focal-plane-shutter slit of the upper camera may also be seen in the upper part of frame A-1, with its leading edge exactly in line with the trailing edge of the focal-plane-shutter slit of the lower camera. Throughout the frames of row A the two focal-plane-shutter slits may be seen to move from left to right relative to the combustion-chamber images.

The lower focal-plane-shutter slit begins to pass across the lower combustion-chamber image at frame A-5. In this same frame the trailing edge of the lower focal-plane-shutter slit and the leading edge of the upper focal-plane-shutter

slit are each indicated by a white arrow and will be seen to be in line with each other as in all other frames of the figure. The focal-plane shutters are assumed to be constructed of a dark material that does not reflect light well; the combustion-chamber image consequently appears gray in all areas where it falls on the focal-plane-shutter material. In frames A-5 to A-8, however, part of the light that forms the lower combustion-chamber image passes through the focal-plane-shutter slit and falls on the photosensitive film; this film, being a bright material that reflects light well, causes the part of the image formed upon it to appear brilliant white in the animation. Hence, in frames A-5 to A-8 the brilliant white part of the picture shows the portion of the lower image uncovered by the focal-plane-shutter slit at each instant.

The lower focal-plane-shutter slit continues to pass across the lower combustion-chamber image from left to right in frames B-1 to B-8. At frame B-8 this slit has passed all the way across the lower image and the exposure of that image is completed. The upper focal-plane-shutter slit begins to pass across the upper combustion-chamber image at frame B-2, with its leading edge still exactly in line with the trailing edge of the lower focal-plane-shutter slit. The upper slit completes its travel across the upper combustion-chamber image at frame C-5, at which time the exposure of this image is complete.

FIGURE I-26.—Animation showing travel of both detonation wave and focal-plane-shutter screen in two still cameras as they might appear if photographed at about 180,000 frames per second. Frames B-2 to B-8 of this figure correspond chronologically with exposure of frames M-11 and M-12 of figure I-5.

In frames B-2 to B-7 of figure I-26 the detonation-wave front may be seen traveling across the upper combustion-chamber image first just a little behind (as indicated by upper white arrow in frame B-2) and later just a little ahead of the leading edge of the upper focal-plane-shutter slit (as indicated by the white arrows in frames B-5, B-6, and B-7), but always quite close to the leading edge of the upper slit. In the same frames (B-2 to B-7) the detonation-wave front may be seen traveling across the lower combustion-chamber image at all times quite close to the trailing edge of the lower focal-plane-shutter slit, first a little behind (as indicated by lower white arrow, frame B-2) and later a little ahead (as indicated by black arrows in frames B-5, B-6, and B-7). As both lower and upper combustion-chamber images (frames M-11 and M-12 of figure I-5) are exposed entirely by light that passes through the upper and lower focal-plane-shutter slits, respectively, during their travel across the images, it is clear from frames B-2 to B-7 of figure I-26 that the upper image (frame M-12 of fig. I-5) when finally developed, will show incandescence over the entire area of the combustion chamber, whereas the lower image (frame M-11 of fig. I-5) will in the main show the same dark mottled combustion zone that is seen in frame M-10 of figure I-5. The only effect the detonation wave will have upon the lower combustion-chamber image (frame M-11 of fig. I-5), as finally developed, will be produced by that part of the detonation wave which travels across the chamber ahead of the trailing edge of the lower focal-plane-shutter slit in frames B-4 to B-7 of figure I-26. Examination of frames B-4 to B-7 shows a very small triangular region of luminosity of gradually increasing size (indicated by black arrows in frames B-5, B-6, and B-7) progressing along the lower right edge of the chamber from left to right. This very small triangular area of luminosity would, in the final developed photograph, produce the white streak along the lower right edge of the chamber, with gradually increasing brilliance toward the right, that is observed in frame M-11 of figure I-5.

In the exposure of frames M-11 and M-12 of figure I-5, the focal-plane-shutter slits moved at a speed of 256 feet per second. The linear dimensions of the actual combustion chamber were 21.5 times as large as those of the combustion-chamber image formed on the film. The detonation wave that produced the effect seen in frames M-11 and M-12 of figure I-5, in the manner illustrated in figures I-25 and I-26, must, therefore, have traveled across the combustion chamber at a speed greater than 6500 feet per second (with due allowance for the fact that the detonation-wave front traveled in a direction at an angle to the direction of motion of the focal-plane shutter.)

If the explosive knock reaction had occurred simultaneously throughout the end gas, as commonly supposed, its luminosity would simply have recorded the relative positions of the trailing edges of the upper and lower focal-plane-shutter slits, consequently the luminosity as seen in frame M-12 of figure I-5 would have extended farther to the left than

the luminosity as seen in frame M-11 by an amount not greater than the width of the focal-plane-shutter slit. The fact that the luminosity visible in frame M-12 extends to the left of the luminosity visible in frame M-11 by an amount greater than the width of the focal-plane-shutter slit precludes the possibility that the luminosity developed simultaneously throughout the chamber. No satisfactory explanation of the appearance of frames M-11 and M-12 of figure I-5 has been advanced other than the explanation illustrated in figures I-25 and I-26. If due consideration is given to the fact that the luminosity visible throughout frame M-12 is quite uniform, and is less than the saturation limit of the photosensitive film, it would seem that each part of frame M-12 must have had about the same exposure to the detonation luminosity and the conditions governing the exposure of the two frames (M-11 and M-12) would, therefore, seem to be mathematically determinate. For these reasons the author believes that the explanation illustrated in figures I-25 and I-26 is the only reasonable explanation of the appearance of these frames.

The effect of the focal-plane shutters of the high-speed camera on apparent velocities of detonation waves is easily shown (reference 10) to comply with the following equation:

$$V = \frac{v V'}{v + V' \cos \alpha}$$

where V is the actual speed of the wave, v the speed of the focal-plane shutter slits, V' the apparent velocity of the wave (progress of the wave between two successive frames, as recorded photographically, divided by nominal time between exposures of the successive frames), and α the angle between the direction of motion of the detonation-wave front and the direction of motion of the focal-plane-shutter slits. (Due regard must be had for the signs of V , V' , and α , as explained in reference 10.) Application of this equation to the case of figure I-27 has given propagation speeds in the neighborhood of 4500 feet per second to the points p_1 , p_2 , . . . p_8 from the point of origin of the knock disturbance (calculated to be at the intersection of line C-C with lines C'-C'). (Fig. I-27 is the same as fig. 7 of reference 10. The complete photographic series and complete treatment are presented in the original paper. The complete photographic series of this combustion process also appears as fig. 8 in reference 5. The engine-operating conditions for this figure were the same as for fig. I-4 of the present paper.)

No correcting equation is required to determine the true detonation-wave velocity from figure I-28, because the front of the detonation wave may be located in three successive frames of this figure at points p_{17} , p_{18} , and p_{19} (wave front position indicated by a bright spot at p_{19}) along a line D-D, which is at right angles to the direction of motion of the focal-plane shutter. The complete treatment of this case (reference 10) yields a value between 3250 and 3400 feet per second for the speed of the detonation wave. (Fig. I-28

FIGURE I-27.—High-speed photographs of development of incandescent spots caused by detonation wave in knocking spark-ignition engine. Fuel, 50 percent S-1 with 50 percent M-2; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; spark plug at top; hot spot at bottom; spark timing, 20° B. T. C.; detonation-wave speed, about 4500 feet per second.

FIGURE I-28.—High-speed photographs of development of luminous area and incandescent spots caused by detonation wave in knocking spark-ignition engine. Fuel, M-1; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; four spark plugs; spark timing, for left-hand plug, 27° B. T. C., for other three plugs, 20° B. T. C.; detonation-wave speed, about 3300 feet per second.

is the same as fig. 13 of reference 10. Additional frames of the series are shown in fig. 12 of that paper as well as in fig. 10 of reference 6. The engine-operating conditions were the same as for fig. I-10 of the present paper except that M-1 reference fuel was used.)

Application of the correcting equation to the explosive knock reactions seen in frame G-12 of figure I-10 and frames G-11 and G-12 of figure I-12 has yielded values in the neighborhood of 6000 and 3600 feet per second, respectively (reference 10). The correcting equation, as well as the qualitative treatment illustrated in figures I-25 and I-26,

yields a value of about 7300 feet per second for the reaction that occurred between frames C-1 and C-2 of figure I-18 after the runaway flame had completed its travel across the chamber. Between these two frames the entire combustion chamber changed from a fairly uniform, dark mottled condition to a fairly uniform white condition. (This change was more evident on the original negative than it is in the printed reproduction. The entire series of photographs was badly underexposed and in copying some of the contrast between frames C-1 and C-2 was lost in order that the frames of rows A and B might be brought out more clearly.) A

uniform change throughout the combustion chamber from a dark mottled condition to a white condition between one frame and the next corresponds to an infinite apparent detonation-wave speed, that is, an infinite value of V' . With an infinite value of V' the correcting equation indicates that the actual detonation-wave velocity is equal to the focal-plane shutter velocity, and in the same direction. Consideration of figure I-26 indicates that a uniform change throughout the combustion chamber would be produced if the detonation wave traveled across the chamber in the same direction and at the same speed as the focal-plane-shutter slit rather than at a slight angle to the direction of motion of the slit and at a slightly higher speed. (The white streak along the lower right edge of the chamber in frame M-11 of fig. I-5 would have been absent if the detonation-wave front had not overtaken the trailing edge of the lower focal-plane-shutter slit at about frame C-19 in fig. I-26 and had not traveled across the chamber slightly ahead of this trailing edge in frames C-19 to D-21; the combustion zone would have been uniformly dark in frame M-11 (fig. I-5) and uniformly white in frame M-12.) For the case of figure I-18 the focal-plane-shutter slits traveled at 251 feet per second in a direction approximately opposite to the travel of the runaway flame in frames B-1 to C-1. The actual linear dimensions of the combustion chamber were 29.2 times as great as the dimensions of the combustion-chamber image. The appearance of figure I-18, therefore, indicates that after the runaway flame completed its travel through the end gas in one direction at about 1900 feet per second a detonation wave passed through the gas in the opposite direction at about 7300 feet per second.

Confirmation of detonation-wave aspect of knock by ultra-high-speed photographs.—Only one motion picture of the knock phenomenon taken with the ultra-high-speed camera (reference 3) is available. This one motion picture, however, taken at the rate of 200,000 frames per second, is confirmatory of the conclusions reached from study of the high-speed photographs taken at 40,000 frames per second. It has not been possible to take more than a very few photographic shots with the ultra-high-speed camera because the high-speed rotating part of the camera, operating in a high vacuum, spatters oil on the 94 glass lenses of the camera to such an extent that the lenses become inoperative after only a few runs. Of 5 or 6 shots that were actually taken at 200,000 frames per second, only one happened to be taken at the right time to cover the knock phenomenon. Further developmental work on the ultra-high-speed camera, which is still proceeding, has been directed toward elimination of the oil-spattering problem.

The ultra-high-speed photographs are shown as a series of 20 still pictures in figure I-29. The combustion process for this series of photographs was fired in the old combustion apparatus with one spark plug in G position (fig. I-1). at

27° B. T. C. The injection valve was at opening J (fig. I-1); the fuel was a blend of 70 percent S-3 with 30 percent M-2 reference fuels; compression ratio, 7.0; and fuel-air ratio, about 0.08. Figure I-29 was previously published as figure 4 in reference 11 and was discussed in that paper more extensively than it will be here.

Before frame A-1 of figure I-29 was exposed the flame had traveled all the way across the chamber in the direction of the arrow that has been drawn in this frame. The whitish area in frames A-1 to A-5, designated B in frame A-3, represents the region in which combustion is complete. The dark (nearly black) areas in these frames, designated F in frame A-3, are the dark mottled combustion zone that has become quite familiar in the high-speed photographs of the earlier figures. The series of figure I-29 did not begin early enough to determine whether any autoignition occurred in this combustion process, but at least at the time of exposure of frame A-1 the entire charge was ignited with the exception of possible small pockets in front of or behind the flame. The boundary between the dark and the light areas, designated R in frame A-2 of the figure, is the *rear* edge of the combustion zone—not the flame front.

The ultra-high-speed camera does not have the focal-plane-shutter effect of the high-speed camera, but has in effect a conventional between-the-lens type of shutter. The exposure time of each frame is roughly the same as the time between successive frames, 5 microseconds, although there is a slight overlapping of exposures, as specified in reference 11. The series of figure I-29 is, therefore, truly representative of events as they occurred in the combustion chamber. Examination of frames A-1 to B-1 of the figure reveals no appreciable change of conditions. Frames A-2, A-4, and B-1 are much more sharply defined than frames A-1, A-3, and A-5. This effect, however, is introduced by the camera and has no significance relative to the burning processes. This alternate blurring of frames can be eliminated in further work with the camera. The first significant change in appearance of the photographs occurs in the area designated by the two arrows in frame B-2. This light area is not present in any of the preceding frames. If this area in frame B-2 is compared with the same area in frame B-1, more difference will be noted than in a like comparison of frame B-1 with frame A-1, five frames preceding. In frames B-3 and B-4, the effect of the knock spreads considerably in all directions from the point of origin. The location of the point of origin at the *rear* edge of the combustion zone is strikingly confirmatory of the conclusion reached from study of the 40,000-frame-per-second photographs that the explosive knock reaction apparently originates in the burning gases rather than in the unignited end gas.

Frames B-1 to B-5 of figure I-29 are reproduced in figure I-30. In figure I-30, however, a black line (R_{B-1}) has been drawn in frame B-1 reinforcing the boundary line between

FIGURE I-29.—Ultra-high-speed photographs (200,000 frames per sec) of phenomenon of knock in spark-ignition engine. Fuel, 70 percent S-3 with 30 percent M-2; compression ratio, 7.0; fuel air ratio, about 0.08; atmospheric intake; one spark plug in G position (fig. I-1); spark timing, 27° B. T. C.

the dark combustion zone on the right and the white burned region on the left. In frames B-2 to B-5 of this figure the same black line has been constructed in each frame, not marking the boundary between burned and unburned as it appears in frames B-2 to B-5 but the boundary as it appeared in frame B-1. In each of the frames B-2 to B-5 two horizontal black lines have been drawn marking the upper and lower extents of the knocking reaction in each frame as indicated by the whitening of the combustion zone to the right of the boundary line R_{B-1} . Distances between the horizontal lines have been designated in each frame as l_2 , l_3 , and so on. Treating the difference between successive values of l as representing the combined upward and downward travel of the knocking disturbance between successive frames (l_1 assumed equal to zero), the following values have been obtained for the speed of the knock disturbance according to the equation:

$$V = \frac{1}{2} \left(\frac{l_2 - l_1}{5 \times 10^{-6}} \right)$$

Frames	Velocity of knocking disturbance (ft/sec)
1 to 2-----	9200
2 to 3-----	4200
3 to 4-----	6900
4 to 5-----	1200

The average of the first three values is nearly 6800 feet per second, which is of the same order as the higher speeds

determined from the high-speed photographs and the speed of 2000 meters per second determined by Sokolik and Voinov in reference 18.

After frame B-4 of figure I-29 the ultra-high-speed photographs no longer show a high speed of propagation of the knock reaction. The portion of the black combustion zone that is still visible in frame B-5 gradually disintegrates throughout the frames of rows C and D, leaving a great many black dots and streaks, which will be discussed later. It is thought either that the areas that still appear black in frame B-5 represent gases that were not in a sufficiently advanced state of combustion to be detonable or that they represent a high concentration of carbon particles resulting from the knock reaction.

Chemical nature of explosive knock reaction.—The high-speed and ultra-high-speed photographs, because of their inherent nature, should not be expected to yield much information concerning the chemical nature of the explosive knock reaction. Two indications have been obtained, however, that may be of the most fundamental importance relative to the chemical nature of the reaction; first, the indication that the reaction results in a definite loss of chemical energy that would otherwise be available, and second, the indication that free carbon is released by the explosive knock reaction. Both of these indications forcibly recall the opinion expressed by Midgley in 1920 (reference 14) that the knocking detonation wave burns only the hydrogen in the hydrocarbon molecule and releases free carbon.

FIGURE I-30.—Frames from figure I-29 outlining actual detonation-wave travel. Detonation-wave speed, about 6800 feet per second both upward and downward from point of origin.

FIGURE I-31.—Pressure-time records for two combustion cycles showing power gain secured by quenching end zone with water to avoid knock.

In figure I-31 are reproduced actual photographs of two pressure-time records obtained with the cathode-ray oscilloscope and a quartz piezoelectric pickup placed at the knocking zone in the combustion apparatus. The manner of obtaining these pressure-time records was fully explained in reference 8. The two traces were taken under identical engine-operating conditions, and with the same fuel (M-3 reference fuel), except that water was injected into the end gas for the "quenched" trace. High-speed photographs were obtained (not reproduced here) showing that the spatial distribution of the injected water coincided fairly well with the remaining combustion zone at the time of knock. As may be observed in the figure the injected water almost eliminated the violent knock that occurred with the unquenched combustion. It is also clear from the figure that the elimination of the knock resulted in a very marked increase in pressure, not only late in the expansion stroke but even immediately after the occurrence of the knock. The comparative traces of figure I-31 are typical of many tests in which the quenched and unquenched combustion cycles followed each other in close succession, and in which the order of taking the quenched and unquenched cycles was repeatedly reversed.

In the ultra-high-speed photographs of figure I-29, a large number of small black spots develop in the frames of row C, both in the dark combustion zone and in the gas that was completely burned before the beginning of the knock development. In the frames of row D these black spots draw out into long narrow streaks in the direction of the mass motion of the gases. Two black spots (C_1 in frame B-1) are visible in the burned gas before the start of knock development, but a very great increase in the number of black spots immediately after the inception of the explosive knock reaction is manifest. Some of the spots, such as C_2 in frame B-5, are visible in the burned gas within 10 microseconds after passage of the knock disturbance through the location of the spots. A number of spots are also visible in the combustion zone in frame B-5 less than 10 microseconds after passage of the knock disturbance.

Black spots and streaks similar to those seen in figure I-29 may be seen in frames J-11 and J-13 of the high-speed photographs presented in figure I-6. The counterpart of the black spots and streaks of frames D-1 to D-5 of figure I-29 and frames J-11 to J-13 of figure I-6 is seen in the

white streaks visible in the frames of figure I-27, which were used to determine the detonation-wave speed in the neighborhood of 4500 feet per second from that figure. The streaks were probably highly incandescent in all cases (figs. I-6, I-27, and I-29). With the ultra-high-speed photographs the exposure time was so short and the lens aperture was sufficiently small so that the incandescence of the streaks did not photograph. The streaks were photographed as black streaks because they were opaque to the externally supplied light by which the photographs were obtained. In the case of figure I-27 the externally supplied light was much less intense and the exposure time was five times greater; consequently, the incandescence of the streaks was photographed and the streaks show up white against the less intense background of externally supplied light. The fact that the spots are black in frames J-11 to J-13 of figure I-6 indicates that these spots were much less incandescent than in the case of figure I-27 obtained under the same photographic conditions. The streaks have probably been lost in many of the photographs because their incandescence has closely matched the brilliance of the externally supplied light.

The facts that approximately circular black spots appeared in the frames of row C in figure I-29 and that these black spots smeared out into streaks in the direction of gas motion in the frames of row D indicate that the material forming these black spots had considerable inertia. Apparently the inertia was sufficient so that the material of the black spots did not go along with the gases in their mass motion: the result was either that the particles were physically smeared out into streaks or the particles caused the precipitation of additional material from the gases flowing by.

Three properties of the material of the black streaks are, therefore, indicated by figures I-27 and I-29; first, the material is incandescent, second, the material is opaque, third, the material is a solid (indicated by its inertia). No substance is known to this author that could be formed from the gases present in the combustion chamber and which would exhibit the three properties stated at the temperature of the gases in the knocking engine except free carbon. It is, of course, well known that excessive free carbon is formed in knocking explosions; the smokiness of the exhaust is often used as a measure of knock. Large quantities of free carbon are deposited on the windows of the combustion apparatuses by a single knocking combustion cycle, as compared with no noticeable carbon deposit by a single nonknocking combustion cycle with the same fuel-air ratio.

The black spots and streaks observed in figures I-6 and I-29, and the corresponding incandescent spots in figure I-27, might be held to be different phenomena. A high-speed photograph has been obtained, however, in which a very large spot appears opaque immediately after the passage of the explosive knock reaction, but later becomes incandescent. Some of the frames of this high-speed photograph appear in figure I-32.* The engine-operating conditions and the fuel for the combustion process of this figure were the same as in the case of figure I-28. At frame A-1 of figure I-32, the normal travel of the flames has passed through most of the chamber; a fair-sized end zone of irregular shape still exists in the central portion of the visible part of the chamber. The end gas is consumed by the normal travel of the flames

FIGURE I-32.—High-speed photographs showing formation of black carbon cloud immediately after knock in spark-ignition engine and later reversal of carbon cloud from black to white. Fuel, M-1; compression ratio, 7.0; fuel-air ratio, about 0.08; atmospheric intake; four spark plugs; spark timing, for left-hand plug, 27° B. T. C., for other three plugs, 20° B. T. C.

between frames A-1 and C-3. The explosive knock reaction begins at frame C-4, as indicated by blurring of parts of the mottled combustion zone. A large black spot is very evident in frames C-7 to C-13 of the figure. Careful inspection of frames C-5 and C-6 reveals that this black spot was beginning to develop in these frames. Between frames D-1 and D-4 the black spot becomes incandescent; in frame D-4 most of the spot is sufficiently incandescent to match the other parts of the combustion chamber. (Non-uniform illumination of the chamber by the externally supplied light is the probable reason why the lowest 20 per cent of the chamber is much less brilliant than the upper parts of the chamber in these frames.) In frames D-5 and D-6 the formerly black spot becomes sufficiently incandescent so that it stands out whiter than the surrounding gases. Between frames D-6 and F-13 parts of this formerly black spot become more and more white as compared with the other gases in the chamber; other parts of the spot apparently cool again and become dark. There is, of course, some gradual change of shape of the spot throughout these frames.

Frames D-6 to about F-8 of figure I-32 have been re-etched

by the engraver to bring out the whiteness of the carbon cloud in contrast with the surrounding gases that are only slightly less white. This re-etching has been done only in order to make the printed reproduction look as nearly as possible like the original untouched photograph in print. Similarly, it was necessary to re-etch several other illustrations to emphasize details that are clearly visible in the photographs but that would have been quite hazy because of the half-tone screen used in the engraving process.

The small spots seen in figures I-27 and I-29, and the large spot in figure I-32, are probably not the only aspect of the free carbon released by the explosive knock reaction. Most of the photographs of heavy knock have shown a very great increase in the general luminosity of the chamber at the time of the explosive knock reaction, amounting in many cases to perhaps a hundredfold increase. This uniform increase in luminosity is probably due to finely divided free carbon. The change is by no means limited to the end gas; it appears to occur throughout the chamber and, if it is concentrated anywhere, it is concentrated at the chamber walls rather than in the end gas. This fact,

together with certain other features of figure I-29 (see reference 11), suggests that the explosive knock reaction may travel through the burned gases in the same manner as the burning gases; such a revolutionary conclusion probably should not be taken very seriously, however, until considerably more evidence is available.

Summary of findings of NACA photographic knock investigations.—The findings of the NACA photographic knock investigations at speeds of 40,000 and 200,000 frames per second over the period from 1939 to 1946 may be summarized as follows:

1. The photographs have shown that normal nonknocking combustion involves an entirely smooth travel of the flames through the combustion chamber and a smooth gradual fadeout of the combustion zones after completion of the flame travel through the chamber.

2. The photographs have indicated that normal combustion involves a zone of continuing combustion behind the flame front with a depth measured in tenths of an inch; the combustion zone, however, may have a cellular structure.

3. The photographs have shown that preignition from a hot spot is not a direct cause of knock and that the flame from a hot spot is similar to the flame from a spark plug.

4. Vibratory knock has been shown to involve an extremely fast reaction, termed the "explosive knock reaction" herein, which develops suddenly after a period of normal burning. This reaction involves a time interval not greater than 50 microseconds.

5. The explosive knock reaction has been shown to begin within 25 microseconds of the same time as the violent knocking vibrations shown by a piezoelectric pickup placed in the end zone of the combustion chamber.

6. The photographs have indicated that the explosive knock reaction originates only in a portion of gas that is already ignited, either by normal flame travel or by autoignition.

7. The photographs have shown a number of different types of end-gas autoignition, some of which appear always to be followed by the explosive knock reaction and some of which may occur without being followed by the explosive knock reaction. The photographs have also shown cases of the explosive knock reaction not preceded by any form of autoignition.

8. Analysis of the photographs taken at 40,000 frames per second has indicated that the explosive knock reaction is a type of detonation wave traveling, under different conditions, at speeds ranging approximately from 3000 to 6500 feet per second or from about one to two times the speed of sound in the burned gases.

9. The propagation speed of the order of 6500 feet per second for the explosive knock reaction has been confirmed by the one series of photographs obtained at 200,000 frames per second.

10. A definite loss of chemical energy that would otherwise have been available has been shown to result from the explosive knock reaction.

11. The photographs have shown that free carbon is released in both the burning and the burned gases within 10 microseconds after passage of the detonation wave associated with the explosive knock reaction.

The indications of the high-speed and ultra-high-speed photographs do not harmonize with the simple autoignition theory of knock or with the simple detonation-wave theory. They appear rather to support the combined detonation-wave and autoignition theory proposed in the literature discussion that forms the first part of this paper.

CHAPTER II

CORRELATIONS OF KNOCK-LIMITED PERFORMANCE DATA

If mechanical limitations are disregarded, the power output of an engine can be increased by varying any one of several operating conditions until the knock limit of the fuel is reached. Once this limit is encountered, further efforts to increase the power will result in overheating of the engine and prolonged operation under these knocking conditions may result in damage to the engine. For these reasons, much research has been conducted to extend knowledge of the nature of knock and, through application of this knowledge, to eliminate knock as an obstacle to greater engine power.

Knock itself is fundamentally related to the following events that occur in the engine cylinder after induction of the fuel-air charge:

1. The fuel-air mixture (charge) is taken into the cylinder at a given temperature and pressure.

2. Compression of the charge begins as the piston moves upward. During this compression the volume occupied by the charge decreases, the pressure increases, and the temperature increases. The total temperature increase includes the temperature rise resulting from an amount of heat transferred from the hot cylinder walls.

3. Ignition of the charge takes place at some point before the piston reaches top center:

4. From the point of ignition the burning charge moves across the cylinder and the flame front compresses the unburned portion of the charge, as illustrated in figure II-1. The arcs emanating from the spark represent progressive positions of the flame front.

5. The density and the temperature in the unburned portion of the charge increase as the flame front progresses.

6. For a given fuel, a unique combination of density and temperature may occur and at this point the unburned portion of the charge will spontaneously ignite (ch. I) with considerable violence to produce the phenomenon called knock.

Rothrock and Biermann (reference 1) assume density and temperature to be the physical properties of the combustion gas that determine whether or not the fuel will knock. For each gas density, a gas temperature exists at which the unburned portion of the charge ahead of the flame front will ignite spontaneously. This combination of density and temperature may or may not be reached, depending upon the controlled and uncontrolled factors of engine operation.

These factors are listed in reference 1 as follows:

- (a) Chemical composition of fuel
- (b) Fuel-air ratio
- (c) Exhaust-gas dilution
- (d) Humidity
- (e) Compression ratio
- (f) Inlet-air temperature
- (g) Inlet-air pressure
- (h) Wall temperature of combustion chamber and cylinder
- (i) Spark advance
- (j) Engine speed
- (k) Engine dimensions
- (l) Combustion-chamber form

If, as pointed out in reference 1, many combinations of density and temperature exist at which a fuel will knock, it is impossible to express the knock limit of a fuel adequately by testing that fuel at only one set of engine operating conditions. Each fuel must be tested under a variety of conditions in order to establish the absolute relation between knock-limited density and temperature. This relation will be the same regardless of the engine in which it is determined.

SYMBOLS

The following symbols are used in this chapter:

a, b	coefficients in specific-heat (constant volume) equation for charge
c_v	specific heat of mixture at constant volume, Btu/(lb)/° F
f	fuel-air ratio
F_1, F_2, F_3	functions
H	heat content per pound of mixture, Btu/(lb)
i	intake cycles per minute
J	mechanical equivalent of heat, 778 (ft-lb)/Btu
K	constant
m	molecular weight of charge
n	moles of gas present in cylinder

FIGURE II-1.—Schematic diagram of travel of flame front across

P	pressure, (lb)/(sq in.)
R	universal gas constant, (ft-lb)/(mole)(°R)
r	compression ratio
T	temperature, °R
T'	mean temperature throughout combustion chamber just before knock, °R
ΔT	temperature rise of cylinder contents due to constant-volume burning, °F
V_c	clearance volume, (cu in.)
V_d	displacement volume, (cu in.)
V_s	specific volume, (cu ft/lb)
W	gas flow, (lb)/cycle
Z	factor replacing $\frac{\rho_c}{T_c^{\frac{\gamma}{\gamma-1}}}$
γ	ratio of specific heats
η_{com}	combustion efficiency
ρ	density, (lb)/(cu in.)
Subscripts:	
b	burned mixture at top center
c	compression
e	effective
k	in knocking zone (end gas) immediately preceding knock
0	inlet air

CORRELATIONS BASED UPON END-GAS CONDITIONS

The last portion of the charge to burn, which under proper conditions of density and temperature ignites spontaneously, is commonly designated the end gas. The space occupied by this gas is called the end zone. From the conventional thermodynamic equations, expressions are derived in reference 1 for determination of the end-gas density and temperature. The compression of the fresh charge admitted to the cylinder occurs in two steps: (1) the charge is adiabatically compressed by the piston until ignition takes place; and (2) the unburned charge ahead of the flame front is assumed to be adiabatically compressed by both the piston and the flame front until knock occurs, or

Step (1):

$$\frac{T_0}{T_c} = \left(\frac{P_0}{P_c} \right)^{\frac{\gamma-1}{\gamma}}$$

Step (2):

$$\frac{T_c}{T_k} = \left(\frac{P_c}{P_k} \right)^{\frac{\gamma-1}{\gamma}}$$

where

T_0, P_0	inlet-air temperature and pressure, respectively
T_c, P_c	temperature and pressure, respectively, after compression by piston
T_k, P_k	temperature and pressure, respectively, in knocking zone immediately preceding knock
γ	ratio of specific heat at constant pressure to specific heat at constant volume

Combining steps 1 and 2 yields

$$T_k = T_0 \left(\frac{P_k}{P_0} \right)^{\frac{\gamma-1}{\gamma}} \quad (1)$$

This equation expresses the temperature in the knocking zone. The expression for density of the unburned charge ahead of the flame front is given by the equation

$$K \rho_k = \frac{P_0}{T_0} \left(\frac{P_k}{P_0} \right)^{\frac{1}{\gamma}} \quad (2)$$

where

ρ_k gas density in knocking zone immediately preceding knock

K constant

Equations (1) and (2) are the same as those of reference 2 except that density has been used instead of pressure.

These equations show that if an engine is operated at conditions of incipient knock and P_k is measured, the density and the temperature may be calculated. Accurate measurements of P_k , however, are very difficult; therefore, the calculations as well as experimentation can be simplified by expressing the density and the temperature in terms of more easily determined factors. For example, equation (2) can be written

$$K \rho_k = \frac{P_0}{T_0} \left(\frac{P_k}{P_c} \frac{P_c}{P_0} \right)^{\frac{1}{\gamma}}$$

If P_c and T_c are the compression pressure and temperature, respectively, and T' is the mean temperature throughout the combustion chamber just before knock occurs, the density ρ_k is expressed by

$$K \rho_k = \frac{P_0}{T_0} \frac{T'}{T_c} \left(\frac{P_c}{P_0} \right)^{\frac{1}{\gamma}}$$

Because

$$T' = T_c + \frac{H}{c_v} = T_0 r^{\gamma-1} + \frac{H}{c_v}$$

and

$$\left(\frac{P_c}{P_0} \right)^{\frac{1}{\gamma}} = r$$

where

H heat content per pound of mixture

c_v specific heat of mixture at constant volume

r compression ratio of engine

then

$$K \rho_k = \frac{r P_0}{T_0} \left(1 + \frac{H}{c_v T_0 r^{\gamma-1}} \right)^{\frac{1}{\gamma}} \quad (3)$$

Similarly,

$$T_k = T_0 r^{\gamma-1} \left(1 + \frac{H}{c_v T_0 r^{\gamma-1}} \right)^{\frac{\gamma-1}{\gamma}} \quad (4)$$

FIGURE II-2.—Effect of estimated end-gas temperature on maximum permissible density factor for leaded and unleaded isooctane in flat-disk combustion chamber. Engine speed, 2500 rpm; improved cooling in cylinder head; fuel-air ratio, 0.081. (Fig. 2 of reference 1.)

In the evaluation (reference 1) of equations (3) and (4), c_p was estimated as 0.25 Btu per pound per °F, γ as 1.29, and H as 1160 Btu per pound of mixture. The quantity H was estimated by the following expression:

$$H = \frac{18,000 \eta_{com} f}{1 + f}$$

where

η_{com} combustion efficiency

f fuel-air ratio

The combustion efficiencies used in reference 1 were obtained from reference 3.

The application of the foregoing relations is illustrated in figure II-2. These data were obtained at an engine speed of 2500 rpm and a fuel-air ratio of 0.081. Although the data represent several compression ratios and several inlet-air temperatures, a single curve is obtained for each fuel. For the range of values examined in reference 1, the value of

$\left(1 + \frac{H}{c_p T_0 r^{\gamma-1}}\right)^{\frac{1}{\gamma}}$ at an inlet-air temperature of 120° F varied from a value of 3.82 at a compression ratio of 6.5 to a value of 3.62 at a compression ratio of 8.75. It was therefore assumed that the density factor (equation (3)) could be expressed by $r P_0 / T_0$. Similarly, the end-gas temperature T_k could be expressed by $T_0 r^{\gamma-1}$. In reference 1, $r^{\gamma-1}$ is also eliminated from the term for T_k because the data justified the omission. Proper consideration of equation (3), however, does not support the elimination of $r^{\gamma-1}$ from equation (4).

The omission of the terms $r^{\gamma-1}$ and $\left(1 + \frac{H}{c_p T_0 r^{\gamma-1}}\right)^{\frac{1}{\gamma}}$ from equation (4) permits the use of T_0 in place of T_k . A comparison of several fuels on this basis is shown in figure II-3. The curves for the fuels tend to converge at high inlet-air tempera-

tures, which indicates that for some temperature it is conceivable that this particular group of fuels might have the same knock-limited performance. This trend is due to the similarity of the fuels used. As will be shown later in this chapter, the curves for various fuels are not ordinarily so similar.

Because the density and temperature relations vary with fuel-air ratio (reference 1), Taylor, Leary, and Diver (reference 4) obtained additional data to improve the accuracy of the expressions in reference 1 and specifically to investigate further the influence of fuel-air ratio. In addition, an effort is made to determine the effect of exhaust-gas dilution on the compression ratio for incipient detonation. As a further refinement of the end-gas conditions, allowance is made for variation of specific heats and chemical equilibrium of the charge before and after combustion with temperature, pressure, and fuel-air ratio. The procedure used for computing end-gas temperatures in reference 4 is as follows:

A point is first selected on the compression stroke of an indicator diagram and the specific volume V_s of the charge is computed. The temperature T_0 is then computed from the following relation:

$$T_0 = \frac{P_0 V_s}{R}$$

where

R gas constant, 1544/m

m molecular weight of charge

FIGURE II-3.—Effect of inlet-air temperature on maximum permissible density factor for series of fuel blends in flat-disk combustion chamber. Engine speed, 2500 rpm; fuel-air ratio, 0.081. (Fig. 4 of reference 1.)

FIGURE II-4.—Comparison of effect of end-gas temperature on maximum permissible end-gas density as determined by methods of references 1 and 4. (Fig. 24 of reference 4.)

The end-gas temperature T_k is calculated from the equation for T_k taken from reference 5.

$$\log T_k = \log T_0 + \frac{R}{\left(a + \frac{R}{J}\right) J} \log \frac{P_k}{P_0} - \frac{b}{2.30 \left(a + \frac{R}{J}\right)} (T_k - T_0) \quad (5)$$

where
 a, b coefficients in specific-heat equation at constant volume for charge

J mechanical equivalent of heat, 778(ft-lb)/Btu

A comparison of the end-gas calculations from references 1 and 4 is shown in figure II-4. The results of these references are in agreement as to the variation of end-gas density with end-gas temperature, but the order of variation of end-gas density with fuel-air ratio at any given end-gas temperature is reversed by the two methods of calculation. An additional analysis by Rothrock cited in reference 4 attributes the apparent reversal of the effect of the fuel-air ratio to the difference between the measured maximum pressures of reference 4 and the computed maximum pressures of reference 1.

The studies of reference 4 were made at constant engine speed and therefore do not consider the effect of time or rate of combustion on knock. In a subsequent investigation, Leary and Taylor (reference 6) attempt to explain the significance of time in engine detonation by the use of indicator diagrams obtained during knock tests. As a result of these studies, the investigators conclude that higher maximum permissible pressures can be used in an engine if the rate of compression of the end gas is increased. This conclusion led to the development of an experimental com-

(a) Variable fuel-air ratio. Compression ratio, 11.7. (Fig. 32 of reference 8.)

FIGURE II-5.—Comparison of isooctane, 100-octane gasoline, triptane, and benzene with respect to variation in ignition delay. Initial pressure, 14.7 pounds per square inch absolute; initial temperature, 149° F; compression time, approximately 0.006 second.

pression machine (reference 7) for use in studies of fuel knocking characteristics.

The first results obtained in the compression machine are reported in reference 8 as an explanation of differences in knocking characteristics of fuels. Ignition delay as a function of fuel-air ratio is shown in figure II-5 (a) for four fuels. When the curves for isooctane (2,2,4-trimethylpentane) and 100-octane gasoline are compared, the ignition delay of the gasoline is seen to be greater than that of isooctane at fuel-air ratios greater than 0.085. The reverse is true at fuel-air ratios below 0.085. On the basis of these results, it is suggested (reference 8) that the knock-limited

(b) Variable compression ratio. Fuel-air ratio, stoichiometric. (Fig. 33 of reference 8.)

FIGURE II-5.—Concluded. Comparison of isooctane, 100-octane gasoline, triptane, and benzene with respect to variation in ignition delay. Initial pressure, 14.7 pounds per square inch absolute; initial temperature, 149° F; compression time, approximately 0.006 second.

performance of these fuels may be similar; that is, isooctane would be higher than 100-octane gasoline at low fuel-air ratios but lower than gasoline at high fuel-air ratios. This belief was confirmed by supercharged knock tests. If ignition delay were the only criterion of knock, it could be concluded from figure II-5 (a) that triptane (2,2,3-trimethylbutane) has the highest antiknock performance with benzene next in order; however, the authors of reference 8 contend that this result may not be true inasmuch as the pressure-time curve during the delay period is also of considerable importance.

Ignition delay as a function of compression ratio is shown in figure II-5 (b). The delay period decreases as the compression ratio increases. The ignition delays for triptane are higher than those of isooctane and 100-octane gasoline over the entire range of compression ratios. Benzene has ignition delays greater than those of triptane at compression ratios below 10.5, but over the entire compression-ratio range the pressure-time records of reference 8 for benzene always indicate a smoother reaction than that of triptane. From this relation it may be surmised that the high-antiknock characteristics of benzene are attributable to the slow pressure rise during combustion of the end gas rather than to the long ignition delay periods.

The correlations of end-gas conditions proposed in references 1 and 4 do not account for variations of fuel-air ratio (fig. II-4); consequently, the end-gas density-temperature relations are rederived in reference 9 with this factor taken into consideration. The following equations are proposed in reference 9:

The density of the charge after adiabatic compression by the piston is

$$\rho_c = \frac{W}{V_c} \quad (6)$$

where

ρ_c density after compression
 W weight of gas inducted per cycle
 V_c clearance volume

The temperature of the charge after compression is

$$T_c = T_0 r^{\gamma-1} \quad (7)$$

The state of the gases before burning in the cylinder when the piston is at top center may be expressed by the ideal gas equation,

$$P_c V_c = n R T_c \quad (8)$$

where

P_c compression pressure
 n moles of gas present in cylinder
 R universal gas constant

The state of the gases at top center after burning is

$$P_b V_c = n R T_b \quad (9)$$

where

P_b pressure of burned mixture at top center
 T_b temperature of burned mixture at top center

Combining equations (8) and (9) gives

$$\frac{P_b}{P_c} = \frac{T_b}{T_c} \quad (10)$$

The end gas is adiabatically compressed during constant-volume combustion

$$\frac{P_{k,e}}{P_c} = \left(\frac{T_{k,e}}{T_c} \right)^{\frac{\gamma}{\gamma-1}} \quad (11)$$

and

$$\frac{\rho_{k,e}}{\rho_c} = \left(\frac{T_{k,e}}{T_c} \right)^{\frac{1}{\gamma-1}} \quad (12)$$

where.

$P_{k,e}$ effective end-gas pressure at instant before knock
 $T_{k,e}$ effective end-gas temperature at instant before knock
 $\rho_{k,e}$ effective end-gas density at instant before knock

The term "effective" was used in reference 9 in referring to the end-gas quantities (subscript k,e) inasmuch as these quantities are based upon an idealized air-cycle analysis and are therefore not the same as the actual values.

As the flame front moves across the cylinder, the unburned gas (assumed to be small) is compressed and knock occurs just before completion of combustion of the entire charge.

In equation (11), P_b can be substituted for $P_{k,e}$

$$\frac{P_b}{P_c} = \left(\frac{T_{k,e}}{T_c} \right)^{\frac{\gamma}{\gamma-1}} \quad (13)$$

Combining equations (10) and (13) yields

$$T_{k,e} = T_c \left(\frac{T_b}{T_c} \right)^{\frac{\gamma-1}{\gamma}} \quad (14)$$

however,

$$T_b = T_c + \Delta T \quad (15)$$

where

ΔT temperature rise of cylinder contents due to constant-volume burning

Therefore,

$$T_{k,e} = T_c \left(1 + \frac{\Delta T}{T_c} \right)^{\frac{\gamma-1}{\gamma}} \quad (16)$$

In reference 9, a relation is assumed to exist between effective end-gas density and effective end-gas temperature at the incipient-knock condition; this relation includes the effects of variations of fuel-air ratio, compression ratio, and inlet-air temperature:

$$\rho_{k,e} = F_1(T_{k,e}) \quad (17)$$

Combining equations (12) and (17) yields

$$\rho_c \left(\frac{T_{k,e}}{T_c} \right)^{\frac{1}{\gamma-1}} = F_1(T_{k,e}) \quad (18)$$

or

$$\frac{\rho_c}{T_c^{\frac{1}{\gamma-1}}} = \frac{F_1(T_{k,e})}{T_{k,e}^{\frac{1}{\gamma-1}}} = F_2(T_{k,e}) \quad (19)$$

Replacing $T_{k,e}$ by its equivalent in equation (16) and letting Z equal $\rho_c/T_c^{\frac{1}{\gamma-1}}$ gives

$$Z = F_2 \left[T_c \left(1 + \frac{\Delta T}{T_c} \right)^{\frac{\gamma-1}{\gamma}} \right] \quad (20)$$

The constant-volume temperature rise during burning ΔT is dependent upon factors such as fuel-air ratio and pressure and temperature of the charge before burning. Of these factors, fuel-air ratio is the most important one affecting ΔT ; therefore, ΔT is considered (reference 9) to be a function of fuel-air ratio alone. At some reference fuel-air ratio, ΔT can be taken as a constant. In reference 9, a fuel-air ratio of 0.08 is selected. A representative value (4040° F) of ΔT is chosen from reference 10 to be used in the correlation of the experimental data of reference 9.

The constant-volume temperature rise due to combustion becomes

$$\Delta T = 4040 F_3(f) \quad (21)$$

where f is fuel-air ratio.

Substituting this value of ΔT into equation (20) gives

$$Z = F_2 \left\{ T_c \left[1 + \frac{4040 F_3(f)}{T_c} \right]^{\frac{\gamma-1}{\gamma}} \right\} \quad (22)$$

FIGURE II-6.—Effect of compression-air temperature and fuel-air ratio on knock-limited values of factor Z for AN-F-28 fuel in CFR engine. Engine speed, 1800 rpm; coolant temperature, 250° F; spark advance, 30° B. T. C. (Fig. 4 of reference 9; data calculated from reference 10.)

213637—53—33

FIGURE II-7.—Effect of fuel-air ratio on function of fuel-air ratio for eight fuels in supercharged CFR engine. (Fig. 5 of reference 9.)

By use of equations (6), (7), (12), (16), and (21), the following expressions may be written for $T_{k,e}$ and $\rho_{k,e}$:

$$T_{k,e} = T_0 r^{\gamma-1} \left[1 + \frac{4040 F_3(f)}{T_0 r^{\gamma-1}} \right]^{\frac{\gamma-1}{\gamma}} \quad (23)$$

$$\rho_{k,e} = \frac{W}{V_{c,r}} \left(\frac{T_{k,e}}{T_0} \right)^{\frac{1}{\gamma-1}} \quad (24)$$

Equations (23) and (24) can be solved for $T_{k,e}$ and $\rho_{k,e}$ if $F_3(f)$ is known. The utility of these equations for correlation of engine variables depends upon whether a single curve results between $T_{k,e}$ and $\rho_{k,e}$, when T_0 , r , or f is varied and also upon the accuracy with which $F_3(f)$ can be evaluated.

In order to determine $F_3(f)$, values of Z are computed (reference 9) from experimental data obtained in a CFR test engine with AN-F-28 (28-R), a 100/130 grade aviation gasoline. The values of Z are computed from $\rho_c/T_c^{\frac{1}{\gamma-1}}$, and a constant γ of 1.4 is used. The computed values are then plotted against T_c as shown in figure II-6. The experimental data upon which this figure is based covered a range of compression ratios from 5 to 10 at a constant inlet-air temperature of 250° F and a range of inlet-air temperatures from 100° to 350° F at a compression ratio of 8. A constant engine speed of 1800 rpm, a coolant temperature of 250° F, and a spark advance of 30° B. T. C., were maintained in all cases.

At constant Z (fig. II-6), a new value of T_c exists for each fuel-air ratio and the right side of equation (22) is constant regardless of fuel-air ratio; consequently, the following equation may be written:

FIGURE II-8.—Variation of knock-limited effective end-gas density with knock-limited effective end-gas temperature for changes in fuel-air ratio, inlet-air temperature, and compression ratio. Inlet-air pressure varied to maintain incipient knock. (Fig. 6 of reference 9; data calculated from reference 12.)

FIGURE II-9.—Effect of change in knock-limited effective end-gas temperature on knock-limited effective end-gas density for eight fuels. (Fig. 8 of reference 9.)

$$T_c \left[1 + \frac{4040 F_3(f)}{T_c} \right]^{\frac{\gamma-1}{\gamma}} = T_{c,0.08} \left(1 + \frac{4040}{T_{c,0.08}} \right)^{\frac{\gamma-1}{\gamma}} \quad (25)$$

The left side of this equation applies for any fuel-air ratio, whereas the right side applies only to the previously mentioned reference fuel-air ratio of 0.08, where $F_3(f)$ has been taken as 1.0. By substitution of different values of T_c from figure II-6 into the left side and the value of T_c for a fuel-air ratio of 0.08 in the right side of equation (25) it is possible to solve for $F_3(f)$.

Values of $F_3(f)$ are determined in reference 9 for seven other fuels and the results are plotted in figure II-7. The curve on this figure represents the mean of the data. Obviously the relation between $F_3(f)$ and f varies with the fuel used and for this reason the use of the mean curve is not recommended unless data for a specific fuel are unavailable.

By means of the $F_3(f)$ curves (fig. II-6) for each fuel, values of $T_{k,e}$ and $\rho_{k,e}$ are calculated (reference 9) from

(a) Knock-limited indicated mean effective pressure. (Fig. 7 of reference 12.)

FIGURE II-10.—Effect of compression ratio and inlet-air temperature on knock-limited performance of diisopropyl plus 4 ml TEL per gallon.

equations (23) and (24). In general, the correlations were quite satisfactory, as illustrated by figure II-8 (a). The poorest correlation was found for triptane (fig. II-8 (b)), particularly at low values of $T_{k,e}$; however, good correlation could not be expected in this case because of the tendency of the fuel to preignite. (See ch. IV.) A comparison of the knock-limited effective density-temperature curves for the fuels investigated is presented in figure II-9.

In order to determine the accuracy of the curves of $T_{k,e}$ against $\rho_{k,e}$, the authors of reference 9 calculated the knock-limited air flow W_a (equation (24)) from $T_{k,e}-\rho_{k,e}$ curves based upon the mean and individual $F_3(f)$ curves of fig-

ure II-7. The results of this comparison are presented in the following table:

Fuel	Mean error in calculated knock-limited charge flow (percent)			
	Variable inlet-air temperature		Variable compression ratio	
	Individual $F_3(f)$	Mean $F_3(f)$	Individual $F_3(f)$	Mean $F_3(f)$
AN-F-28 (28-R).....	3.5	4.2	4.6	5.5
Aviation alkylate.....	2.9	6.4	3.9	5.4
S reference.....	2.7	7.6	3.7	7.0
Diisopropyl.....	3.7	5.0	4.0	3.9
Triptane.....	8.6	24.4	6.6	22.4
Cyclopentane.....	7.3	7.2	7.5	8.6
Cyclohexane.....	5.1	7.4	7.2	9.0
Triptene.....	6.0	8.5	6.2	6.6

As would be expected, the least error in the calculated air flow resulted from use of the curves of $T_{k,e}$ against $\rho_{k,e}$ based upon the individual $F_3(f)$ curves. Diisopropyl at variable compression-ratio conditions and cyclopentane at variable inlet-air-temperature conditions appear to be exceptions, but the difference in mean error is small between the air flows computed from individual or mean $F_3(f)$ curves.

(b) Knock-limited air flow.

FIGURE II-10.—Concluded. Effect of compression ratio and inlet-air temperature on knock-limited performance of diisopropyl plus 4 ml TEL per gallon.

FIGURE II-11.—Effect of compression temperature on knock-limited compression-air density for diisopropyl plus 4 ml TEL per gallon. (Fig. 16 of reference 12.)

CORRELATIONS BASED UPON COMPRESSION CONDITIONS

The calculation of end-gas temperatures and densities described in the foregoing section is sufficiently complicated and uncertain to make it desirable to use some simple method of data correlation. One such method, based upon compression conditions, is proposed in reference 11. The method does not correlate all the variables of engine operation such as spark advance, engine speed, or fuel-air ratio, but is useful in explaining the effects of compression ratio and inlet-air temperature on fuel performance.

In this method, a relation is assumed to exist between compression conditions before ignition occurs and end-gas conditions after ignition occurs; therefore, calculated compression densities and temperatures may be used in place of end-gas densities and temperatures.

The compression density may be calculated as follows:

$$\rho_c = \frac{W_0}{i V_c} = \frac{W_0(r-1)}{i V_d} \quad (26)$$

where

W_0 inlet-air flow, (lb/min)
 i intake cycles per minute

V_c clearance volume, (cu in.)

V_d displacement volume, (cu in.)

The calculation of compression temperature (reference 11) neglects the effects of fuel vaporization, heat transfer to the cylinder walls, fuel-air ratio, and preflame reactions; however, the correlations obtained with an adiabatic-compression formula justify these omissions.

$$T_c = T_0 r^{\gamma-1} \quad (27)$$

In order to verify this method of correlation, knock-limited performance data were obtained for a number of fuels in references 11 and 12. These data resulted from tests in which all operating conditions except compression ratio were held constant. The tests were then repeated with all variables except inlet-air temperature constant. An illustration of the engine data for a single fuel is presented in figure II-10. Compression densities and temperatures calculated from data in these figures are shown in figure II-11. Comparisons of several fuels (reference 13) are shown in figure II-12.

The curves shown in these figures illustrate the relative sensitivities of fuels to changes of temperature and compression ratio and also may be used to describe the popular terms "mild" and "severe" conditions. For example (fig. II-12 (a)), an increase in compression ratio or inlet-air temperature causes an increase in compression temperature and a decrease in knock-limited performance as indicated by the low compression densities. Any combination of engine operating variables, such as spark advance, inlet-air temperature, compression ratio, and engine speed, that tends to produce exceptionally low knock-limited compression densities, is commonly termed a "severe" condition. Conversely, "mild" conditions tend to produce high knock-limited compression densities.

The type of curve shown in figure II-12 (a) has also been used to express the term "temperature sensitivity." Although no universally accepted definition of temperature sensitivity has been devised, the authors of reference 12 suggest that the compression-density-temperature plot offers a more generally applicable definition than any other yet devised. The slope of the curve of compression density plotted against compression temperature would offer a measurement of temperature sensitivity. Calculations of these slopes for the fuels investigated in reference 12 indicated that the temperature sensitivities of isooctane, aviation gasoline, an aviation alkylate, and diisopropyl (2,3-dimethylbutane) were very nearly independent of engine conditions. The temperature sensitivity of triptane decreased as the severity of the engine conditions decreased; the temperature sensitivities of cyclopentane, cyclohexane, triptene, (2,3,3-trimethylbutene-1), and toluene increased as the severity of the engine conditions decreased.

(a) Fuel-air ratio, 0.065.

(b) Fuel-air ratio, 0.11.

FIGURE II-12.—Temperature-density relations for various fuels in CFR engine. Engine speed, 1800 rpm; coolant temperature, 250° F; spark advance, 30° B. T. C. (Fig. 7 of reference 13.)

FIGURE II-13.—Temperature-density relations for two fuels in R-2600 cylinder. Engine speed, 2100 rpm; spark advance, 20° B. T. C.; rear spark-plug-bushing temperature, 450° F. (Fig. 8 of reference 13.)

The data presented in figure II-12 were obtained in a CFR engine that is designed to permit variation of compression ratio. In order to determine if the compression-density—temperature correlation would hold for full-scale engines, similar tests were made in an experimental engine employing a single cylinder from an aircraft engine. The compression ratio was varied by using pistons of different displacement in the cylinder. The results of these runs (reference 13) are shown in figure II-13.

Inasmuch as the correlation is satisfactory for full-scale engines (fig. II-13), the experimental evaluation of engines or fuels can be minimized. For example, investigation of the effect of compression ratio on knock-limited performance

in full-scale multicylinder engines is impractical because of the cost, time, and effort involved in changing pistons. Curves like those of figure II-13, however, can be established with relative ease by varying inlet-air temperature. From the curve so established, the effect of compression ratio on knock-limited compression density can be calculated from assumed compression temperatures.

Although the simplicity of the compression-density—temperature correlation is greater than that of the end-gas correlations presented in the preceding section of this chapter, the end-gas method has the obvious advantage of compensating for variations in fuel-air ratio as well as for compression ratio and inlet-air temperature.

CHAPTER III

ANTIKNOCK PERFORMANCE SCALES

For many years the efforts of investigators in the field of fuel research have been directed toward the development of suitable scales for measuring the knocking characteristics of fuels. As a result of these efforts, a number of scales have been studied, but only a few have passed beyond the stage of tentative acceptance. The emphasis in this development has generally been placed upon one objective—that the method permit the assignment of a numerical antiknock value to each fuel and that the rating so determined be reasonably constant regardless of the engine or operating condition used.

The achievement of this objective has been hindered because the many fuels suitable for aviation use vary widely in their response to changes in engine conditions and also because the rating scales currently used are unsatisfactory for rating fuels in the high performance range. As a result of these difficulties, attention has been turned in recent years to the problem of establishing a rating scale that will permit determination of ratings for high-performance fuels. An effort has been made in these studies to select reference fuels that will respond to changes in engine conditions in a manner similar to that of service fuels. The material in this chapter is given in greater detail in reference 1.

DEVELOPMENT OF FUEL-RATING SCALES

Octane scale.—One of the earliest and the most enduring knock-rating scales is the familiar octane-number scale proposed by Edgar (reference 2) in 1927. This scale is based on two reference fuels, isooctane (2,2,4-trimethylpentane) and *n*-heptane, suggested because isooctane knocked less and *n*-heptane more than any other fuels then known. In this system, isooctane is arbitrarily assigned a rating (octane number) of 100 and *n*-heptane, a rating of 0. The characteristic shape of curves representing the octane scale is shown in figure III-1 from data obtained in the A. S. T. M. Supercharge engine (A. S. T. M. designation D909-47T).

The octane scale is restricted to the determination of ratings for fuels producing knock-limited power equal to or less than that of isooctane and equal to or greater than that of *n*-heptane. At the lower end of the scale, the limitation offers no serious obstacle because interest in fuels with greater knocking tendencies than *n*-heptane is purely academic. On the other hand, the upper or isooctane end of the scale offers a very serious obstacle inasmuch as many pure hydrocarbons and commercial blending stocks are known to exceed the knock-limited power output of isooctane.

In addition to being limited in use to fuels having antiknock values between those of *n*-heptane and isooctane, the octane scale fails to provide numerical ratings that remain

constant from engine to engine or from one condition to another. That is, a fuel having an octane number of 80 in one engine may have an octane number of 90 in another engine. Investigation has shown, however, that the ratings of paraffinic fuels, with the exception of certain highly branched isomers, tend to remain more nearly constant from engine to engine than do widely different types of hydrocarbon within the range of performance covered by the octane scale (reference 3). This fact can be attributed to the differences in sensitivities of various fuels to changes in operating conditions. Inasmuch as the rating fuels (isooctane and *n*-heptane) are paraffinic, these fuels would be expected to respond to changes in operating conditions in much the same manner as a paraffinic test fuel. If, on the other hand, the test fuel contains large concentrations of aromatic, cycloparaffinic, or olefinic compounds, the response to variations in operating conditions would differ greatly from the behavior of the paraffinic rating fuels.

FIGURE III-1.—Octane scale determined on A. S. T. M. Supercharge engine at standard conditions. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 375° F; spark advance, 45° B. T. C. (Fig. 1 of reference 1.)

Lead scale.—When fuels with knock ratings that exceeded the upper limit of the octane scale were first considered for service use, it became apparent that the octane scale was no longer adequate for rating aviation fuels; consequently, the search began for a performance scale that would accommodate the high-performance fuels used in modern aircraft power plants. In order to meet this problem, it was decided that fuels exceeding the performance of isooctane should be matched against isooctane to which had been added a given amount of tetraethyl lead. (See fig. III-2.) The procedure for rating fuels by the lead scale is the same as that used for the octane scale; that is, the knock intensity of the test fuel is determined in a standard engine at standard conditions and the knocking tendencies of blends of isooctane and tetraethyl lead are compared with those of the test fuel until one blend is found to give a knock intensity equal to that of the test fuel.

Performance-number scale.—Neither the octane scale nor the lead scale permitted the assignment of a numerical rating indicative of the power output of a fuel, and in an effort to circumvent this difficulty a scale of performance numbers was adopted. The performance scale (fig. III-3) represents an approximate average of the knock-limited performance as determined in several different engines at differ-

FIGURE III-2.—Lead rating scale determined on A. S. T. M. Supercharge engine at standard conditions. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 375° F; spark advance, 45° B. T. C. (Fig. 2 of reference 1.)

FIGURE III-3.—Performance-number scale. (Fig. 3 of reference 1.)

ent operating conditions for isooctane containing various amounts of tetraethyl lead. Although empirically determined, this scale has proved useful in expressing fuel ratings and in correlating performance of fuels in different engines, but it still does not provide an absolute measure of power output.

The performance-number scale does not alter the procedure for rating fuels by use of leaded isooctane (lead scale) but does change the method of reporting the rating. For example, if a test fuel is found to give knock-limited performance equal to isooctane plus 2.0 ml TEL per gallon in any engine at any condition, its rating is reported as 138 performance number. (See fig. III-3.)

The performance scale as originally adopted was intended for use only with fuels having ratings above an octane number of 100 by the A. S. T. M. Supercharge method. General acceptance of the scale soon led to expression of ratings by the A. S. T. M. Aviation method (A. S. T. M. designation D614-47T) in terms of performance numbers and later resulted in extension of the scale below a performance number of 100.

Proposed rating scales.—One limitation of the octane scale and the lead scale is that the service fuels containing an approximately constant amount of tetraethyl lead (3.0 to 4.6 ml/gal) must be matched against unleaded rating fuels or against rating fuels having variable concentrations of lead. This limitation is inherently related to the problem of fuel sensitivity to changes in operating conditions in that tetraethyl lead affects the sensitivity of the fuel to which it is added.

In order to minimize this effect on fuel ratings, investigators in the field have proposed rating scales in which the reference fuels contain a constant amount of tetraethyl lead in the range of concentrations found in service fuels. Some of these schemes recommend the addition of a third component, such as an aromatic, in the reference fuel blend in order to produce reference fuels having sensitivities more nearly equal to service fuels.

EVALUATION OF PROPOSED FUEL-RATING SCALES

On the basis of studies made by the Coordinating Research Council (reference 4), it was proposed that triptane (2,2,3-trimethylbutane) and *n*-heptane be adopted as the reference fuels for a new rating scale. Both fuels were to contain 3.78 ml TEL per gallon. The studies on which this proposal was based were conducted in A. S. T. M. Aviation and A. S. T. M. Supercharge fuel-rating engines at standard operating conditions. In order to extend the data of the Coordinating Research Council beyond standard operating conditions, an investigation of the proposed rating scale over a range of engine conditions was conducted by the NACA and is reported in reference 1. The results of this investigation of triptane and *n*-heptane were compared with results obtained under similar test conditions for current rating scales and other proposed scales.

The effects of varying engine conditions were simulated by varying inlet-air temperature from 100° to 300° F in the A. S. T. M. Supercharge engine. The combinations of reference fuels investigated were:

1. Isooctane and *n*-heptane
2. Isooctane (containing 0 to 6 ml TEL/gal)
3. Isooctane and *n*-heptane (both containing 3.78 ml TEL/gal).

^b Lean ratings by A. S. T. M. Aviation method are intended to be indicative of "cruise" performance. Rich ratings by A. S. T. M. Supercharge method are intended to be indicative of take-off performance. (See reference 5.)

4. Triptane and *n*-heptane (both containing 3.78 ml TEL/gal)

5. Triptane and isooctane (both containing 3.78 ml TEL/gal)

In order to compare the merits of the various rating scales, several service and service-type fuels were included in the investigation. (See table III-1.) In choosing these particular fuels and blends, an effort was made to cover a wide range of performance numbers both rich and lean. Inspection properties for these fuels are presented in table III-2.

Although complete knock-limited mixture-response curves were obtained in the A. S. T. M. Supercharge engine, the analysis of results presented (reference 1) is restricted to two fuel-air ratios, 0.065 and 0.11. Examples of data at these two fuel-air ratios are shown in figure III-4.

The points on the curves in these figures are cross-plotted from mixture-response curves.

Antiknock ratings made by the A. S. T. M. Aviation method for the various reference-fuel blends are presented in table III-3.

Comparisons among various reference scales.—In figure III-5 the various reference scales are compared at standard A. S. T. M. Aviation and A. S. T. M. Supercharge operating conditions. It is seen in figure III-5 (a) that for A. S. T. M. Aviation conditions the data for leaded blends of isooctane and *n*-heptane fall on a 45° line, which indicates that the A. S. T. M. Aviation (lean) rating of isooctane containing 3.78 ml TEL per gallon is equal to that of triptane containing the same quantity of tetraethyl lead. Conversely, data at A. S. T. M. Supercharge (rich) conditions (fig. III-5 (b)) show that for equal knock-limited indicated mean effective pressures more isooctane is required than triptane in leaded blends with *n*-heptane. In figure III-5 (b) it is shown that between 80 and 84 percent triptane in a blend with *n*-heptane (leaded) would be required to equal the upper limit (161) of the current performance scale.

An additional observation can be made from figure III-5: namely, that for A. S. T. M. Aviation conditions the two-component reference-fuel systems with constant tetraethyl-lead concentrations are related by straight lines, whereas at A. S. T. M. Supercharge conditions definite curvature is obtained.

Temperature sensitivity of reference fuels.—As a measure of the temperature sensitivity of the reference-fuel combinations, the slopes of curves similar to those in figure III-4 for all the reference-fuel combinations were computed at an inlet-air temperature of 225° F (standard A. S. T. M. Supercharge conditions) and plotted against the knock-limited mean effective pressures at the same temperature. These plots were made for fuel-air ratios of 0.065 and 0.11 and are shown in figure III-6. A single curve was drawn through each set of points (lean and rich) to illustrate the variation of temperature sensitivity with knock-limited performance for the various reference-fuel blends. The different portions of the curve determined by individual reference-fuel combinations are also indicated on figure III-6.

Above the upper limit of the current performance-number scale (fig. III-6), the sensitivity increases rapidly as the knock-limited indicated mean effective pressure increases. If this trend is generally true for service-type fuels, it is apparent from this figure that such fuels having high knock limits should be matched against leaded blends of triptane and isooctane or triptane and n-heptane in order to have reference fuels and service fuels of comparable sensitivity. For lower performance fuels, however, any of the reference scales indicated would be suitable from sensitivity considerations.

Temperature sensitivity of service-type fuels.—The effects of inlet-air temperature on the knock-limited performance of the service-type fuels (table III-1) were also investigated in the A. S. T. M. Supercharge engine. The slopes of the temperature-sensitivity curves (reference 1) were computed at 225° F and plotted in the same manner described for figure III-6. The result is shown in figure III-7 with the curves from figure III-6 reproduced for comparison.

The points representing service fuels (fig. III-7) lie primarily above the curves established for the reference fuels. This divergence is attributed to the fact that the service fuels are blends containing a number of different components; whereas the reference-fuel blends are composed of only two components. Insofar as a perfect rating scale is concerned, the ideal condition would be for the service-fuel data to fall directly on the reference-fuel curve.

FIGURE III-7.—Comparison among the temperature sensitivities of reference-fuel blends and service-type fuels in A. S. T. M. Supercharge engine. * Table IV of reference 1.

^b Imep, knock-limited indicated mean effective pressure; ON, octane number; PN, performance number; LIH, blend of iso-octane and *n*-heptane containing 3.78 ml TEL/gal; LTH, blend of triptane and *n*-heptane containing 3.78 ml TEL/gal; LTI, blend of triptane and iso-octane containing 3.78 ml TEL/gal.^c Octane numbers and performance numbers obtained by the standard A. S. T. M. Aviation rating procedure. Ratings in terms of other scales estimated from fig. III-5(a).

Because this situation is improbable, the next best solution must be for reference-fuel blends and service fuels to have sensitivities of approximately the same magnitude at the same knock-limited performance levels. The attainment of this characteristic can be approached by the use of either the joint reference scale, leaded triptane-iso-octane and leaded iso-octane-*n*-heptane, or by the leaded triptane-*n*-heptane scale (fig. III-7).

In evaluating the merits of a rating scale, however, three factors other than temperature sensitivity must be considered, namely that the scale should:

(1) Be a continuous scale

(2) Involve a minimum number of reference fuels

(3) Cover the complete range of knock-limited performance likely to be encountered with a variety of service fuels.

In figures III-6 and III-7, it has been shown that both the leaded triptane-*n*-heptane scale and the joint scale of leaded iso-octane-*n*-heptane and leaded triptane-iso-octane have the last of these characteristics. Only the leaded triptane-*n*-heptane scale, however, possesses the first two characteristics as well; consequently, this scale appears to be the most practical choice. The problem of availability of reference fuels is obviously important but is beyond the scope of the investigation reported in reference 1.

FIGURE III-9.—Maximum knock-limited mean effective pressures attainable for various fuels by A. S. T. M. Supercharge method without encountering preignition. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 375° F; spark advance, 45° B. T. C. (Fig. 21 of reference 1.)

Ratings of service-type fuels.—The 10 service-type fuels were assigned ratings in terms of the 5 reference scales examined in this investigation. These ratings are given in table III-4 for standard A. S. T. M. Aviation conditions and for A. S. T. M. Supercharge conditions at five inlet-air temperatures and two fuel-air ratios. The ratings in this table were determined for comparing the constancy of the assigned ratings by the different rating scales over a range of conditions established by varying inlet-air temperature. This comparison is presented in figure III-8 for the A. S. T. M. Supercharge engine at a fuel-air ratio of 0.11.

These figures alone cannot serve as a basis for choosing the best reference scale because the constancy of an assigned rating from one set of operating conditions to another is largely dependent upon the relative sensitivities of reference fuels and test fuels previously discussed.

Limitations of reference scales.—In the preceding discussion, it has been stated that in many cases knock-limited indicated mean effective pressures were not obtained for some of the higher-performance service-type and reference fuels investigated in the A. S. T. M. Supercharge engine. The attainment of complete data for high-performance fuels was hampered throughout the investigation by the tendency of these fuels to preignite in the A. S. T. M. Supercharge engine. The engine operator at all times obtained as much of the mixture-response curve as possible before the start of preignition (see ch. IV); for some fuels, however, points richer than a fuel-air ratio of about 0.08 could not be taken. Inasmuch as the peaks of the curves were not obtained, ratings could not be made in the fuel-air-ratio range characteristic of the standard A. S. T. M. Supercharge method.

Preignition occurred with the high-performance fuels regardless of the condition of the engine; changing the type of spark plug failed to prevent preignition.

Preignition was encountered so frequently that early data obtained in the NACA laboratories were examined in order to define the range of indicated mean effective pressure in which preignition is likely to occur in the A. S. T. M. Supercharge engine. The results of this study are presented in figure III-9, together with data from the present investigation. Each point on this plot represents the richest point of a mixture-response curve that could be obtained before the occurrence of preignition. It is seen in figure III-9 that with several fuels it was possible to reach preignition-free performance at indicated mean effective pressures greater than 400 pounds per square inch; however, a number of fuels preignited at levels below 400 down to about 258 pounds per square inch. In most cases, the limiting fuel-air ratios were leaner than the fuel-air-ratio range in which A. S. T. M. Supercharge ratings are usually made.

Inasmuch as preignition imposes a very real limit on an A. S. T. M. Supercharge rating scale at a rich fuel-air ratio, the maximum indicated mean effective pressures that can be obtained with current and proposed reference scales are indicated in figure III-9. The difference between scales is about 75 pounds per square inch indicated mean effective pressure; the adoption of either reference scale utilizing triptane as one of the components will thus extend the range in which "direct-match" ratings can be made by about 75 pounds per square inch. Even then there will be some fuels (as indicated by preignition test points in fig. III-9) that cannot be rated in this range. In fact, only three of the five service-type fuels exceeding a performance number of 161 could be rated (shown as solid lines between fuel-air ratios of 0.10 and 0.12 in fig. III-9). The remaining two fuels having performance numbers over 161 preignited at fuel-air ratios leaner than 0.08 (indicated by the square data points on fig. III-9).

If the A. S. T. M. Aviation and A. S. T. M. Supercharge engines are to continue in use as the standard fuel-rating engines, the advantages to be gained by the adoption of new reference-fuel systems utilizing triptane are clearly questionable, as pointed out by the authors of reference 1. The present scale of performance numbers has been shown to permit ratings for fuels up to a performance number of 161 in the A. S. T. M. Aviation engine; triptane plus 3.78 ml TEL per gallon, which represents the maximum performance of either of the proposed reference-fuel combinations, permits ratings only up to a performance number of 151. Moreover, in the A. S. T. M. Supercharge engine the tendencies of many high-performance service-type fuels and high-performance reference-fuel blends to preignite makes the advantage of extending the range in which ratings can be made in this engine somewhat uncertain.

CHAPTER IV

PREIGNITION

Over a period of years research directed toward increasing engine power has been paralleled by research in engine cooling. This pattern of investigation arises from the occurrence of mechanical failures in engine cylinders when certain established temperature limits are exceeded. Opinions vary as to the principal danger of high cylinder temperatures; however, final cylinder failure obviously results from high temperatures, high pressures, or both (reference 1). The initial cause of failure may be knock, preignition, or failure of sealing devices, such as piston rings and valves, but the sequence in which the events leading up to failure occur will vary with operating conditions, design features, and fuel.

In an effort to clarify the exact roles played by these factors in service operation, this chapter presents a discussion of NACA investigations in which the characteristics of preignition are studied and the relation of preignition and knock to engine temperatures is analyzed.

CHARACTERISTICS OF PREIGNITION

Preignition and knock.—A hot spot in an engine cylinder may cause ignition of the fuel-air charge in the cylinder prior to ignition by the spark plug. This phenomenon is known as preignition. Preignition and knock are separate phenomena, as indicated by Rothrock and Biermann (reference 2). If, as suggested by this investigation, the occurrence of knock depends upon the density and the temperature of the last portion of the charge to burn, it is reasonable to assume that preignition which causes the end gas to burn nearer top center also tends to promote fuel knock, whereas preignition which causes the end gas to burn well before top center may lessen the possibility of fuel knock. In reference 1, this theory is thus concluded to provide one explanation of why preignition is often accompanied by knock and why, in other cases, in which preignition may be severe enough to cause immediate engine failure, fuel knock may not be present. A specific case of this nature is reported in reference 3.

Run-away and stable preignition.—Run-away and stable preignition are defined by Hundere and Bert (reference 4) in terms of the rate of increase of the hot-spot temperature and the required temperature for surface ignition. If, for example, the hot-spot temperature increases much more rapidly than the required surface temperature for ignition, run-away preignition occurs. When this situation exists, the ignition of the fuel-air charge may advance more and more until ignition takes place in the intake duct; a backfire then occurs.

On the other hand, stable preignition is obtained when the required surface temperature for ignition increases more rapidly than the actual hot-spot temperature. A point is then reached where the required temperature and the actual temperature are equal, and stable ignition occurs. In this case, the ignition system may be inoperative and the engine will operate normally; ignition is then accomplished solely by the hot spot in the cylinder.

Preignition characteristics vary with fuel type; for some fuels, such as benzene, preignition may become severe enough to wreck an engine cylinder so quickly that no appreciable increase in temperature or decrease in engine output can be observed.

EFFECTS OF ENGINE VARIABLES ON PREIGNITION

An investigation reported by Corrington and Fisher (reference 5) was undertaken to obtain information on the behavior of an engine during preignition operation. Spark plugs of various heat ranges were used as sources of preignition in most of the tests of reference 5. In some cases, however, preignition was excited by exhaust valves. A valve having a badly corroded head was installed in place of the Nichrome coated valves normally employed; cold-operating spark plugs were used.

Preignition was excited at various fuel-air ratios, power levels, engine speeds, and mixture temperatures.

The investigation reported in reference 5 was made in a single, liquid-cooled engine cylinder. The setup consisted of a multicylinder engine block mounted in such a manner that any one cylinder could be used. Details of the installation and the methods of instrumentation are described in references 5 and 6.

Reproducibility of preignition runs.—Cylinder design and the location and heat capacity of the preignition source are factors that influence the behavior of an engine during preignition operation. Reproducibility of preignition data will be imperfect, however, even if these factors and all operating conditions are held constant. For the studies in which spark plugs initiated preignition (reference 5), the cause of irreproducibility was the time required for the preignition to advance from normal spark timing to a point about 60° B. T. C. On occasional cycles, a run would start with ignition a few degrees early. The ignition time became earlier as the cycles with early ignition occurred more frequently. Cylinder temperature rose slowly during this period of operation. When the ignition time had advanced to about 60° B. T. C., the preignition process was greatly accelerated and successive runs were fairly reproducible. The time required was 30 to 60 seconds for preignition to become advanced to this critical value (60° B. T. C.). It is suggested in reference 5 that this variation in time to reach the critical value may result either from changes in condition of the spark plug due to deposits and corrosion or errors in setting the engine conditions.

Typical preignition runs.—Data from typical preignition runs are shown in figure IV-1. The location of the zero point on the abscissa has no significance inasmuch as the curves were adjusted on the time scale so that the points coincided where preignition became rapidly accelerated. This arrangement eliminates the period of poor reproducibility from consideration.

FIGURE IV-1.—Typical preignition runs indicating reproducibility of data in full-scale single-cylinder engine. Compression ratio, 6.65; engine speed, 3000 rpm; mixture temperature, 175° F. coolant temperature, 250° F; spark advance: inlet, 28° B. T. C.; outlet, 34° B. T. C.; fuel-air ratio, 0.070; preignition source, spark plug in exhaust side. (Fig. 4 of reference 5.)

FIGURE IV-2.—Full-scale single-cylinder test-engine induction system. (Fig. 2 of reference 5.)

The curves in figure IV-1 represent the averages of the individual runs and may be considered typical of engine operation during preignition at a given set of conditions. All curves discussed in succeeding paragraphs have been obtained in the same manner from several runs at each operating condition.

The preignition run in figure IV-1 was terminated by backfiring, as was true for most of the runs conducted in reference 5. Backfiring occurs when the time of ignition is considerably earlier than that at which the intake valves close (118° B. T. C.). The flame cannot pass into the induction system unless a pressure rise occurs sufficient to slow down or to reverse the flow through the intake valves.

After a backfire, the fuel-air charge in the vaporization tank (fig. IV-2) burned and the resulting pressure rise caused reversal of the air flow at the tank entrance. Because the fuel was injected at this point, the flame burned out quickly. Combustion in the cylinder was reestablished after about 1 second, but the preignition source was sufficiently hot to cause early ignition again. Backfiring continued at intervals until a change in the operating conditions cooled the preignition source.

At high power output and fuel-air ratios leaner than 0.095, preignition caused backfiring. Preignition was stable at richer mixtures and ignition occurred near bottom center.

Effect of fuel-air ratio on preignition.—Fuel-air ratio, because of its influence on combustion temperatures and rate

of burning, is one of the important variables to be considered during preignition operation. The effect of fuel-air ratio on preignition is illustrated in figure IV-3. As seen in figure IV-3, the time of ignition at the lean fuel-air ratio (0.070) advanced to about 220° B. T. C. (40° B. B. C.) about 7 seconds after the start of the rapidly advancing preignition period. The time of ignition at the start of this period was about 48° B. T. C. At the rich fuel-air ratio (0.099), the time of ignition advanced less rapidly than at the lean fuel-air ratio and became stable at about 150° to 160° B. T. C. No backfire occurred at the rich fuel-air ratio.

The increase in peak pressure was about 20 percent at the lean fuel-air ratio and 25 percent at the rich fuel-air ratio; according to reference 5, however, these increases are in doubt because of scatter in the experimental data.

The power output (fig. IV-3) dropped sharply during the period of preignition. During the same period the cylinder-head temperatures increased sharply. As pointed out in reference 5, the piston temperature might be expected to follow curves similar to those shown for the cylinder-head temperature with the possibility that the temperature rise might be even greater.

Effect of power output on preignition.—The effect of engine power level on preignition is shown in figure IV-4. In order to obtain these data, it was necessary (reference 5) to use spark plugs of three different heat ranges. The results of these tests indicate that the time before backfiring increased as the power level decreased. This result is consistent with the decrease in cyclic temperatures as the power decreased, as indicated by the cylinder-head temperatures (fig. IV-4). The percentage increase in peak cylinder pressures increased as the power level decreased.

FIGURE IV-3.—Effect of fuel-air ratio on engine behavior during preignition. Compression ratio, 6.65; engine speed, 3000 rpm; mixture temperature, 175° F; coolant temperature, 250° F; spark advance: inlet, 28° B. T. C.; outlet, 34° B. T. C.; preignition source, spark plug in exhaust side. (Fig. 5 of reference 5.)

FIGURE IV-4.—Effect of power output on engine behavior during preignition. Compression ratio, 6.65; engine speed, 3000 rpm; mixture temperature, 175° F; coolant temperature, 250° F; spark advance: inlet, 28° B. T. C.; outlet, 34° B. T. C.; fuel-air ratio, 0.070; pre-ignition source, spark plug in exhaust side. (Fig. 6 of reference 5.)

FIGURE IV-5.—Effect of engine speed on engine behavior during preignition. Compression ratio, 6.65; mixture temperature, 175° F; coolant temperature, 250° F; spark advance: inlet, 28° B. T. C.; outlet, 34° B. T. C.; fuel-air ratio, 0.070; pre-ignition source, spark plug in exhaust side. (Fig. 8 of reference 5.)

Effect of engine speed on preignition.—Preignition data obtained at two engine speeds are shown in figure IV-5.

FIGURE IV-6.—Effect of mixture temperature on engine behavior during preignition. Compression ratio, 6.65; engine speed, 3000 rpm; coolant temperature, 250° F; spark advance: inlet, 28° B. T. C.; outlet, 34° B. T. C.; fuel-air ratio, 0.070; preignition source, spark plug in exhaust side. (Fig. 9 of reference 5.)

FIGURE IV-7.—Effect of preignition source on engine behavior during preignition. Compression ratio, 6.65; engine speed, 3000 rpm; mixture temperature, 175° F; coolant temperature, 250° F; spark advance: inlet, 28° B. T. C.; outlet, 34° B. T. C.; fuel-air ratio, 0.070. (Fig. 10 of reference 5.)

These two runs were made at about the same power level. Backfires were encountered in both cases at about the same time of ignition (195° B. T. C.).

The peak cylinder pressure increased about 15 and 25 percent at engine speeds of 2000 and 3000 rpm, respectively. This difference can be partly explained by the increase in the heat transferred per cycle at the lower engine speed. (See reference 5.) The cylinder-head-temperature rise (fig. IV-5) was less at the lower speed because backfiring occurred sooner.

Effect of mixture temperature on preignition.—Little difference was found in the preignition behavior of the engine that could be attributed to the influence of mixture temperature (fig. IV-6). At a mixture temperature of 175°F , the peak pressures were higher than at 275°F . The time-of-ignition curve at 275°F is incomplete because of difficulties with instrumentation. (See reference 5.)

(a) Piston failure. Clearance between top of piston skirt and cylinder barrel, 0.004 inch less than normal; imep, 271 pounds per square inch; fuel-air ratio, 0.098.

FIGURE IV-8.—Exhaust-side view of pistons after preignition runs. (Fig. 12 of reference 5.)

(b) Piston failure. Clearance between top of piston skirt and cylinder barrel, normal (0.021 in.); imep, 364 pounds per square inch; fuel-air ratio, 0.094.

FIGURE IV-8.—Continued. Exhaust-side view of pistons after preignition runs. (Fig. 12 of reference 5.)

(c) Piston failure. Clearance between top of piston skirt and cylinder barrel, 0.005 inch greater than normal; imep, 364 pounds per square inch; fuel-air ratio, 0.094.

FIGURE IV-8.—Continued. Exhaust-side view of pistons after preignition runs. (Fig. 12 of reference 5.)

(d) Undamaged piston. Clearance between top of piston skirt and cylinder barrel, 0.013 inch greater than normal; imep, 392 pounds per square inch.

FIGURE IV-8.—Concluded. Exhaust-side view of pistons after preignition runs. (Fig. 12 of reference 5.)

Effect of ignition source on preignition.—In order to evaluate the effect of ignition source on preignition, two runs were made that employed a hot spark plug in one case and a hot exhaust valve in the other. The resulting data are shown in figure IV-7. Preignition advanced more slowly with the exhaust valve as the source; however, backfire was

(a) Exhaust valve after run of figure IV-8 (b). (Fig. 14 of reference 5.)

FIGURE IV-9.—Damage to engine components during piston failures in preignition runs.

encountered sooner when the spark plug initiated the preignition. The peak-pressure increase and the power decrease were greater when the spark plug served as the source of preignition.

Types of failure caused by preignition.—Typical examples of piston failures are shown in figure IV-8. These failures occurred in runs with reduced piston cooling and at generally

higher power levels than those of the runs described in the preceding paragraphs.

The first failure (fig. IV-8 (a)) resulted from a run in which the clearance between piston and cylinder was about 0.004 inch less than normal (0.021 in.) for the engine. In this case the piston seized and the side of the piston melted. With normal clearance (fig. IV-8 (b)) a higher power level was necessary to cause failure. This failure differed from the failure shown in figure IV-8 (a) in that local melting took place in the center of the piston crown. The failure shown in figure IV-8 (c) resulted from a run with the clearance 0.005 inch greater than normal. More local melting in the center of the piston crown was found with this clearance than was found in the run with normal clearance (fig. IV-8 (b)). In the last run (fig. IV-8 (d)), the clearance was increased 0.013 inch greater than normal and seizure and subsequent failure were not experienced at the power level investigated.

Examples of failures to other cylinder parts are shown in figure IV-9. The exhaust valve (fig. IV-9 (a)) burned during the run in which the piston failure in figure IV-8 (b) was encountered. The valve failure is attributed (reference 5) to particles of aluminum or other substance lodging between the valve and the valve seat. The cylinder barrel (fig. IV-9 (b)) was damaged when the piston shown in figure IV-8 (c) failed. The hot gases caused burning through the barrel into the coolant passage.

(b) Cylinder barrel after run of figure IV-8 (c). (Fig. 15 of reference 5.)

FIGURE IV-11.—Hot spots employed in preignition studies.

PREIGNITION CHARACTERISTICS OF FUELS

The nature of preignition and the behavior of an engine during preignition operation has been discussed; the influence of fuels on preignition is now considered. The fundamental relations that govern the preignition of fuels are studied in references 7 to 9. The results as cited by Male and Evvard (reference 10) indicate that the hot-spot "threshold" temperature required to produce preignition is relatively insensitive to fuel composition. The ability of a fuel to heat an engine hot spot to the preignition temperature by normal or surface combustion, however, was found dependent upon

FIGURE IV-12.—Preignition limits of fuels in supercharged CFR engine. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 100° F; coolant temperature, 250° F; spark advance, 32° B. T. C.; preignition source, finned hot spot. (Fig. 4 of reference 10.)

fuel composition, operating conditions, and design of engine and hot spot.

The investigation reported in reference 10 was intended to demonstrate the preignition-limited performance of several fuels. A later investigation reported by Male (reference 11) illustrates how the preignition-limited performance of fuels is affected by engine operating conditions. Both these investigations were conducted on small-scale engines.

Preignition limits of several fuels.—For the study of preignition-limited performance of fuels (reference 10), a supercharged CFR engine with an aluminum piston and a sodium-cooled exhaust valve were used. The intake valve was shrouded (180° shroud) and was installed as shown in figure IV-10. According to reference 10, the shrouded valve aids in isolating the effects of preignition from the effects of knock.

FIGURE IV-13.—Preignition limits of fuels in supercharged CFR engine. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 250° F; spark advance, 20° B. T. C.; preignition source, open-tube hot spot. (Fig. 5 of reference 10.)

This fact is substantiated by unpublished data showing that a shrouded intake valve decreases the sensitivity of thermal-plug temperatures to knock. In order to follow the changing pressure diagram during preignition and to detect knock, a magnetostriction pickup unit was used in conjunction with a cathode-ray oscilloscope. The position of this pickup unit is shown in figure IV-10. (See reference 10.)

The two types of hot spot used in reference 10 are shown in figure IV-11. For tests in which the finned hot spot (fig. IV-11 (a)) was used, the inlet-air temperature was 100° F and the spark advance was 32° B. T. C. The inlet-air

temperature was 225° F and the spark advance 20° B. T. C. for the tests in which the open-tube hot spot (fig. IV-11 (b)) was used.

Preignition-limited performance data for five fuels at two sets of engine conditions are shown in figures IV-12 and IV-13. In general, the curves of preignition-limited indicated mean effective pressure have similar shapes with the minimum power points occurring at fuel-air ratios richer than stoichiometric. Between fuel-air ratios of about 0.070 to 0.085 the relative performance of the fuels in order of decreasing performance was

S reference fuel+4 ml TEL/gal
AN-F-29 (100/140 grade)
S reference fuel
Benzene
Diisobutylene

The over-all spread in indicated mean effective pressure for the five fuels was greater in figure IV-13 than in figure IV-12. This difference and the change in order of benzene and diisobutylene at mixtures richer than 0.085 is attributed (reference 10) to differences in the hot spots, or conditions, or both.

In figures IV-12 and IV-13, the reproducibility of preignition data is demonstrated by check points on the curve for unleaded S reference fuel. The deviations of the data points from the faired curve are about the same as those found in determinations of knock-limited performance.

At constant inlet-air pressures, the maximum thermal-plug temperatures were determined for the fuels (reference 10). This step was considered necessary because the ability of a fuel to increase general engine temperatures might affect the preignition characteristics of the fuel. Preignition-limited fuel-air ratios (fig. IV-12) and thermal-plug temperatures at corresponding inlet-air pressures are shown in the following table:

Fuel	Inlet-air pressure, in. Hg abs					
	20		30		40	
	Thermal-plug temperature * (° F)	Preignition-limited fuel-air ratio ^b	Thermal-plug temperature * (° F)	Preignition-limited fuel-air ratio ^b	Thermal-plug temperature * (° F)	Preignition-limited fuel-air ratio ^b
Benzene.....	561	0.123	669	0.135	761	0.141
Diisobutylene.....	541	.106	649	.123	735	.133
S reference fuel.....	523	.093	631	.110	715	.118
AN-F-29.....	537	.089	641	.114	728	.125
S reference fuel+4 ml TEL.....	520	-----	631	.108	715	.118

* Observed at fuel-air ratio for maximum thermal-plug temperature.
^b Data taken from fig. IV-12.

It was concluded (reference 10) from these data that thermal-plug temperatures do not offer a dependable basis for establishing fuel preignition ratings. This conclusion was drawn from the investigations of S reference fuel in which it was found that the same thermal-plug temperatures were obtained with and without tetraethyl lead, although the preignition-limited-performance curves were different (fig. IV-12).

The presence of tetraethyl lead in S reference fuel appears (fig. IV-12) to increase the preignition-limited performance. A similar investigation in which triptane was used showed the same trend (fig. IV-14). Also shown in figure IV-14 is a curve representing the preignition-limited performance of AN-F-28 (28-R) aviation gasoline. The preignition-limited performance of this fuel is very nearly the same as that of triptane containing 4 ml TEL per gallon. This result is of interest inasmuch as the knock-limited performance of triptane is considerably greater than that of AN-F-28 fuel under most operating conditions. (See ch. II.) A curve for S reference fuel is included in figure IV-14 for comparison. This curve was determined at the time of the triptane and AN-F-28 runs and is slightly different from the S reference fuel curves in figures IV-12 and IV-13.

Preignition limits of aromatic amines.—The effects of six aromatic amines on the preignition-limited performance of AN-F-28 (28-R) fuel were investigated in reference 12.

FIGURE IV-14.—Comparison of preignition limits of triptane (leaded and unleaded) with preignition limits of other fuels in supercharged CFR engine. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 250° F; spark advance, 20° B. T. C.; preignition source, open-tube hot spot. (Fig. 6 of reference 10.)

FIGURE IV-15.—Effect of compression ratio on preignition limits in supercharged CFR engine. Engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 250° F; spark advance, 20° B. T. C.; preignition source, open-tube hot spot. (Fig. 14 of reference 11.)

In this study, blends of AN-F-28 (28-R) fuel containing 2 percent by weight of the following amines were prepared and tested: xylidines, cumidines, N-methylxylidines, N-methylcumidines, N-methylaniline, and N-methyltoluidines. A CFR engine was used for these experiments. Pertinent details of the setup have been mentioned in connection with the runs shown in figures IV-12 to IV-14. A more complete description is presented in reference 11.

FIGURE IV-16.—Effect of spark advance on preignition limits in supercharged CFR engine. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; coolant temperature, 250° F; preignition source, open-tube hot spot. (Fig. 15 of reference 11.)

The results of the investigation of reference 12 are presented in the following table in the form of ratios of preignition-limited indicated mean effective pressures of the six blends to that of AN-F-28 (28-R) fuel. This basis of comparison was chosen in order to eliminate effects of day-to-day variations in performance of the engine as well as differences arising from changes in the hot spot.

FIGURE IV-17.—Effect of inlet-air temperature on preignition limits in supercharged CFR engine. Compression ratio, 7.0; engine speed, 1800 rpm; coolant temperature, 250° F; spark advance, 20° B. T. C.; preignition source, open-tube hot spot. (Fig. 16 of reference 11.)

Aromatic amine added to AN-F-28 (28-R) (2 percent by weight)	Fuel-air ratio				
	0.06	0.07	0.08	0.09	0.10
	imep ratio *				
None.....	1.00	1.00	1.00	1.00	1.00
N-methylaniline.....	1.02	.98	.99	.99	1.01
N-methyltoluidines.....	.91	.92	.94	.97	.99
Xylidines.....	.96	.95	.96	1.00	1.02
N-methylxylidines.....	.98	.98	.98	.99	1.00
Cumidines.....	.95	.91	.91	.91	.91
N-methylcumidines.....	.92	.90	.96	.97	.99

* Ratio of imep of blend to imep of 28-R fuel.

Of the aromatic amines examined in reference 12, N-methylaniline and N-methylxylidines had the highest preignition limits; however, within the experimental accuracy of these tests, the preignition limits of these two aromatic amines appear to be equal to the preignition limit

FIGURE IV-18.—Effect of coolant temperature on preignition limits in supercharged CFR engine. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 225° F; spark advance, 20° B. T. C.; preignition source, open-tube hot spot. (Fig. 17 of reference 11.)

FIGURE IV-19.—Effect of engine speed on preignition limits in supercharged CFR engine. Compression ratio, 7.0; inlet-air temperature, 225° F; coolant temperature, 250° F; spark advance, 20° B. T. C.; preignition source, open-tube hot spot. (Fig. 18 of reference 11.)

of the base fuel, AN-F-28 (28-R). At lean fuel-air ratios, the remaining aromatic amines lowered the preignition limit of AN-F-28 (28-R) fuel about 2 to 10 percent. At rich fuel-air ratios, the cumidines lowered the preignition limit of AN-F-28 (28-R) fuel about 9 percent, whereas the other aromatic amines had little or no effect on the base fuel.

EFFECT OF ENGINE VARIABLES ON PREIGNITION-LIMITED PERFORMANCE

The influence of engine operating variables on preignition-limited performance is illustrated in reference 11. The study was made in a supercharged CFR engine; the following three fuels were used: S reference fuel, diisobutylene, and benzene. The hot spot was an open-tube type. (See fig. IV-11 (b).)

Effect of compression ratio on preignition limit.—The variation of preignition-limited indicated mean effective pressure with compression ratio is shown in figure IV-15. For the three fuels examined, the preignition-limited performance decreased as the compression ratio increased. At the stoichiometric fuel-air ratio, this change for the fuels varied between approximately 7 and 12 pounds per square inch per unit change in compression ratio. The decrease in preignition limits may be attributed to the increase in cyclic temperatures as the compression ratio is increased.

Effect of spark advance on preignition limit.—In figure IV-16, the preignition-limited indicated mean effective pressure is seen to decrease as the spark was advanced. Among the fuels this decrease was about 0.5 to 4 pounds per square inch per degree of spark advance at stoichiometric mixtures. The magnitude of this spread in indicated mean effective pressure among the fuels results from the fact that the sensitivity of diisobutylene to changes of spark advance is so different from the sensitivity of the other fuels (fig. IV-16).

Effect of inlet-air temperature on preignition limit.—The effect of inlet-air temperature on preignition-limited performance is illustrated in figure IV-17. The slopes of the curves for the three fuels are very similar. At stoichiometric mixtures, the decrease in preignition-limited indicated mean effective pressure in these experiments was about 0.1 to 0.3 pound per square inch per °F. Here again the decrease in preignition limits can be attributed to increased cyclic temperatures.

Effect of coolant temperature on preignition limit.—The effect of coolant temperature on preignition limits of the three fuels was determined by using three different coolants in an evaporative cooling system. The coolants used were water, ethylene glycol, and a mixture of water and ethylene glycol. The results of these tests are shown in figure IV-18.

As shown in figure IV-18, the preignition-limited performance decreased as the coolant temperature was increased; however, as emphasized in reference 11, the effect is not solely a temperature effect but includes also the effect of

differences in heat-transfer characteristics of the three coolants.

Effect of engine speed on preignition limit.—The results of runs in which the effect of engine speed on preignition-limited performance were investigated are shown in figure IV-19. Many of these curves, especially those near stoichiometric mixtures, pass through a minimum. At the stoichiometric mixture, minimum values of preignition-limited indicated mean effective pressure were found at engine speeds between 1500 and 2100 rpm.

CHAPTER V

HYDROCARBONS AND ETHERS AS ANTIKNOCK BLENDING AGENTS

Improvements in aircraft power plants during the past 30 years have resulted in demands for fuels of increasingly high antiknock performance. This trend has necessitated a thorough investigation of possible high-antiknock compounds that may or may not occur naturally in petroleum. The task of surveying an endless procession of possible fuel-blending agents has fallen to the petroleum industry and interested research groups. Through the combined efforts of the organizations concerned, a large quantity of data has been amassed. These data permit an accurate appraisal of the merits of many chemical compounds heretofore given little more than cursory consideration as fuel-blending agents.

As a participant in this field of research, the NACA in 1937 sponsored a project by the National Bureau of Standards for the preparation of 1-liter quantities of selected paraffins and olefins. The engine evaluation of the antiknock qualities of these compounds was first conducted under the sponsorship of the American Petroleum Institute (API) and the results of this work have been reported by Lovell (reference 1). In addition, the API has sponsored a synthesis program conducted at the laboratories of Ohio State University. All these programs have been continued up to the present and were augmented during 1942-47 by additional synthesis and engine evaluation at the NACA Lewis laboratory.

The synthesis project at the National Bureau of Standards has been devoted to compounds in the paraffinic and olefinic classes; the synthesis project at the NACA Lewis laboratory has been devoted to compounds in the aromatic and ether classes; and the synthesis program at Ohio State University has been devoted to compounds in these and other classes.

The engine evaluation of pure compounds sponsored by the API was conducted in laboratories of the General Motors Corp. and the Ethyl Corp. The engine evaluation of blends reported in this chapter was conducted at the NACA Lewis laboratory.

Results of the NACA study of paraffins, olefins, aromatics, and ethers are published in a number of reports (references 2 to 14); each report contains data for several compounds on factors such as blending characteristics, temperature sensitivity, lead response, and relation between molecular structure and antiknock ratings. In the succeeding sections of this chapter the effects of molecular structure on these factors of performance are discussed.

ENGINES AND EXPERIMENTAL CONDITIONS

The engine evaluation of the antiknock characteristics of organic compounds was conducted in four test engines: (1) a CFR engine conforming to specifications for the A. S. T. M. Aviation method (D614-47T) for rating fuels; (2) CFR engine conforming to specifications for the A. S. T. M. Supercharge method (D909-47T) for rating fuels; (3) an engine having a displacement of 17.6 cubic inches (about half that of a CFR engine) and popularly known as the 17.6

engine; and (4) a full-scale air-cooled aircraft cylinder mounted on a CUE crankcase.

The 17.6 and A. S. T. M. Supercharge engines were equipped with dual fuel systems, one line for the "warm-up fuel" and one for the test fuel. Knocking was detected in both engines by means of a cathode-ray oscilloscope in conjunction with a magnetostriction pickup unit.

The full-scale single-cylinder test engine was fitted with baffles and cooling air was directed toward the cylinder in order to simulate cooling conditions in flight. Further details of the full-scale installation are given in reference 2.

Pertinent operating conditions for the various engines are presented in table V-1. The 17.6 engine was operated at two inlet-air temperatures, 100° and 250° F, in order to obtain an indication of the sensitivity of fuels to changes in temperature. When the inlet-air temperature was varied, all other conditions were held the same as shown in table V-1.

TABLE V-1.—ENGINE OPERATING CONDITIONS

Cooling-air temperature, ^b °F	-----	-----	-----	85	85

* Approximate.

^b Cooling-air flow was determined by running engine at brake mean effective pressure of 140 lb/sq in. and fuel-air ratio of 0.10 and by adjusting air flow until temperature of rear spark-plug bushing was 365° F.

The conditions shown in table V-1 for the A. S. T. M. Aviation and A. S. T. M. Supercharge engines are standard for these engines when antiknock ratings are being determined. As indicated in table V-1, the A. S. T. M. Aviation engine is a nonsupercharged engine in which the compression ratio is varied in order to determine the knock limit of a given fuel at a lean fuel-air ratio with all conditions other than compression ratio held reasonably constant. On the other hand, the A. S. T. M. Supercharge engine is operated with all conditions except inlet-air pressure and fuel-air ratio held constant. Knock limits are determined by varying the manifold pressure until knocking occurs. Although the fuel-air ratio can be varied for this engine, antiknock ratings are made at a rich fuel-air ratio, usually about 0.11. The A. S. T. M. Aviation method (lean ratings) may thus be indicative of fuel performance at cruise conditions; whereas the A. S. T. M. Supercharge method (rich ratings) may be indicative of take-off performance.

The full-scale engine conditions were proposed by the Coordinating Research Council in an effort to standardize full-scale single-cylinder experimental engine operation throughout the country. During the early stages of the NACA investigation, fuels were investigated in the full-scale single-cylinder engine (quantity permitting), but these methods were later abandoned when it became apparent that the small-scale engine adequately described the fuel performance.

COMPOUNDS INVESTIGATED

The compounds investigated included 13 branched paraffins, 5 branched olefins, 27 aromatics, and 22 ethers. The paraffins and olefins examined were in the C_5 to C_9 molecular-weight range; the aromatics were in the C_6 to C_{12} range; and the ethers were in the C_4 to C_{11} range.

The individual compounds, together with physical properties determined by the National Bureau of Standards or the NACA Lewis Laboratory, are listed in table V-2.

* Approximate value (decomposed on atmospheric boiling).

BASE FUELS

Inasmuch as limited quantities of the compounds were available, all tests were conducted on blends rather than on the pure compound. By this procedure, considerable information could be obtained with a relatively small quantity of a given compound. The pure fuels were investigated in blends with two base fuels, one of which was S reference fuel. The other was a blend of 85 percent (by volume) S reference fuel and 15 percent M reference fuel. This blend contained 4.0 ml TEL per gallon. For all practical purposes, S reference fuel is pure isooctane and M reference fuel is a straight-run stock of about 20 octane number (A. S. T. M. Motor method). Use of this base blend was discontinued during the investigation and a blend of 87½ percent S reference fuel and 12½ percent *n*-heptane was substituted. This blend, too, contained 4.0 ml TEL per gallon.

The performance rating of the leaded blend of S and M reference fuels was about 113/108, whereas the rating of the leaded blend of S reference fuel and *n*-heptane was about 120/112.

PRESENTATION OF DATA

The antiknock performance data for all blends and base fuels are presented in appendix A, tables A-1 to A-8. In many cases the performance values have been adjusted to compensate for differences in the base blend used. Where these adjustments have been made, the values will obviously disagree with values reported in references 2 to 14; however, for the purposes herein, the data as a whole have been placed on a more uniform basis.

The previously mentioned adjustments, in effect, permit treatment of the data as if only two base fuels had been used, namely, isooctane (leaded and unleaded) and a leaded blend of isooctane and *n*-heptane.

RELATION BETWEEN MOLECULAR STRUCTURE AND ANTIKNOCK CHARACTERISTICS

A large part of past research relating to molecular structure and antiknock behavior has been summarized by Lovell (reference 1) and by Lovell and Campbell (reference 16).

In both these investigations, an attempt was made to secure generalizations that would assist in the prediction of relative antiknock values from molecular structures. The past studies have on the whole been very successful in this respect. As this particular phase of fuel research has progressed, however, the basic knowledge of engine performance has advanced; consequently, exceptions to these generalizations can and do exist by virtue of differences in engines and engine operating conditions. That is, the relative antiknock characteristics of a given group of fuels can be changed considerably by altering the engine or experimental conditions.

As a result, the concept of "severe" and "mild" engine conditions has been devised as an aid in evaluating the merits of different fuels. A severe condition is one in which controlled conditions such as inlet-air temperature, coolant temperature, compression ratio, spark advance, and engine speed combine in their effects to make a fuel knock more readily. (See ch. II.) In reference 14, the various engine operating conditions used in the NACA investigation of ethers are alined into a relative order of severity. This same order of severity is used in the present discussion and is presented in table V-3.

TABLE V-3.—DEGREE OF SEVERITY OF VARIOUS OPERATING CONDITIONS

Engine	Mixture condition	Degree of severity
A. S. T. M. Aviation	Lean	Severe.
Full-scale take-off	do	Moderate to severe.
A. S. T. M. Supercharge	Rich	Moderate.
Full-scale take-off	do	Do.
Full-scale cruise	Lean	Do.
17.6 (inlet-air temperature, 250° F)	do	Do.
Full-scale cruise	Rich	Moderate to mild.
17.6 (inlet-air temperature, 250° F)	do	Do.
17.6 (inlet-air temperature, 100° F)	Lean	Do.
17.6 (inlet-air temperature, 100° F)	Rich	Mild.

Because of this so-called severity concept, any statement to the effect that one fuel performs better than another fuel has little significance unless it is true for all operating conditions or restricted to one operating condition. For this reason, the emphasis in an investigation of the type reported

(a) Engine, A. S. T. M. Aviation.

FIGURE V-1.—Knock-limited performance of paraffins in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

herein must be placed upon the trends in the relation between structure and knock rating that appear to apply under most conditions.

Paraffins.—Data were obtained for 13 paraffinic hydrocarbons in leaded blends with the mixed base fuel. Inasmuch as the quantities of hydrocarbon were somewhat limited, all the paraffins were compared only at the 25-percent (by volume) concentration level and only at standard A. S. T. M. Aviation and A. S. T. M. Supercharge conditions (appendix A, table A-1 (a)). The data for these blends are shown in figure V-1.

This figure illustrates the relation between molecular structure and antiknock performance for the paraffins investigated. The lines joining the various data points are shown merely to define the paths followed by compounds in an homologous series. An increase of one carbon atom on the abscissa of these figures is equivalent to a molecular-weight increase equal to the molecular weight of a CH_2 group.

At the A. S. T. M. Aviation conditions (fig. V-1 (a)),

(b) Engine, A. S. T. M. Supercharge.

FIGURE V-1.—Concluded. Knock-limited performance of paraffins in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

seven of the paraffinic hydrocarbons raised the knock-limited performance of the base fuel. The increases varied between 2 and 15 performance numbers with 2,2,3-trimethylbutane (triptane) having the highest rating. This result indicates that under severe conditions, represented by the A. S. T. M. Aviation (lean) method, triptane has outstanding antiknock characteristics.

Insofar as the effect of molecular structure on antiknock characteristics is concerned, three trends have been emphasized (references 1 and 16). The first trend is concerned with centralization of the molecule. For example, 2,2,3,3-tetramethylbutane is a more centralized or compact molecule than 2,2,3-trimethylpentane and should therefore have a higher antiknock rating. The second trend shows the effect of adding methyl (CH_3) groups to a molecule in order to form successive members of an homologous series. The addition of a methyl group to increase the branching tends to produce a compound having a higher antiknock rating; however, the position in which the group is added to the molecule will influence the rating of the new compound. This effect, based on A. S. T. M. Aviation antiknock ratings for the blends examined in the present investigation, is illustrated as follows:

The third trend is concerned with the increase in length of a carbon side chain or the primary carbon chain of a molecule. The effect of such an addition is to decrease the antiknock rating as illustrated by the following examples:

In general, the trends reported in references 1 and 16 and discussed in the preceding paragraph (fig. V-1 (a)) appear to be valid at mild or moderate engine operating conditions. At severe operating conditions, however, exceptions do occur as regards centralization of the molecule or increased branching in the molecule.

At the A. S. T. M. Supercharge conditions, which, as indicated in table V-3, are of moderate severity, the NACA data (fig. V-1 (b)) agree substantially with the results found by Lovell (reference 1). In this case (fig. V-1 (b)), 12 of the 13 paraffinic hydrocarbons investigated raised the knock-limited performance of the base fuel; the increases were in the range of 2 to 44 performance numbers. The antiknock rating of the blend containing 2,2,3,3-tetramethylpentane was the highest obtained and the triptane blend was next.

In order to illustrate the fact that increased centralization of the molecule does not always result in high antiknock values, the A. S. T. M. Aviation ratings are plotted against the A. S. T. M. Supercharge ratings for five nonanes blended with the mixed base fuel in figure V-2. If, in this figure, 2,2,3,3-tetramethylpentane is considered the most compact molecule and 2,2,4,4-tetramethylpentane the least compact, then it is apparent (because the correlating line has a negative slope) that increasing compactness may improve antiknock performance under one set of conditions and depreciate antiknock performance at other conditions. As previously mentioned, the addition of methyl groups, that is, increased branching, does not always result in improved performance. This fact is illustrated by the following A. S. T. M. Aviation ratings:

It is emphasized, however, that these exceptions appear to exist at severe operating conditions as exemplified by the A. S. T. M. Aviation engine.

Olefins.—Five olefins were examined in leaded blends with the mixed base fuel at standard A. S. T. M. Aviation and A. S. T. M. Supercharge conditions (appendix A, table A-1 (a)). The concentration of olefin in each blend was 25 percent by volume.

The data obtained are somewhat limited insofar as the relation between molecular structure and antiknock value is concerned; however, comparisons can be made with references 1 and 16 to determine further the consistency of trends noted by previous investigators. Lovell (reference 1) found that for branched aliphatic compounds if the parent paraffin hydrocarbon had a high antiknock value the introduction of a double bond would decrease the antiknock value. This

FIGURE V-2.—Relation between A. S. T. M. Supercharge and A. S. T. M. Aviation performance numbers of nonanes in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

trend is supported by the following data from the present investigation (appendix A, table A-1 (a)):

Paraffin	Performance number of 25-percent blend *		Olefin	Performance number of 25-percent blend *	
	A. S. T. M. Aviation	A. S. T. M. Supercharge		A. S. T. M. Aviation	A. S. T. M. Supercharge
$\begin{array}{c} \text{C} \quad \text{C} \\ \quad \\ \text{C}-\text{C}-\text{C}-\text{C}-\text{C} \end{array}$	118	114	$\begin{array}{c} \text{C} \quad \text{C} \\ \quad \\ \text{C}-\text{C}=\text{C}-\text{C}-\text{C} \end{array}$	100	117
$\begin{array}{c} \text{C} \quad \text{C} \quad \text{C} \\ \quad \quad \\ \text{C}-\text{C}-\text{C}-\text{C}-\text{C} \end{array}$	122	132	$\begin{array}{c} \text{C} \quad \text{C} \quad \text{C} \\ \quad \quad \\ \text{C}-\text{C}=\text{C}-\text{C}-\text{C} \end{array}$	101	104
$\begin{array}{c} \text{C} \quad \text{C} \\ \quad \\ \text{C}-\text{C}-\text{C}-\text{C}-\text{C} \\ \\ \text{C} \end{array}$	130	141	$\begin{array}{c} \text{C} \quad \text{C} \\ \quad \\ \text{C}-\text{C}=\text{C}-\text{C}-\text{C} \\ \\ \text{C} \end{array}$	106	108

* All blends were leaded to 4 ml TEL/gal.

FIGURE V-3.—Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

In the foregoing examples, the double bond in the olefin appeared in the 2 position and, with one exception, the ratings for the olefins are lower than those of the corresponding paraffins. The one exception is shown for the A. S. T. M. Supercharge ratings of 2,3-dimethylpentane and 2,3-dimethyl-2-pentene where the olefin has an antiknock rating three performance numbers higher than the paraffin.

Of the five olefins investigated, only two, 2,4,4-trimethyl-1-pentene and 2,4,4-trimethyl-2-pentene, indicate the effect of the position of the double bond on antiknock performance. For the engines and the conditions examined (appendix A, tables A-1 (a) and A-5 (a)), the ratings of these two compounds appear to be the same at the more severe conditions. At milder conditions, the 2,4,4-trimethyl-2-pentene has lower ratings than 2,4,4-trimethyl-1-pentene. This trend is contrary to the trend found for straight-chain olefins but is in agreement with data for branched-chain olefins (reference 1).

Aromatics.—The most complete set of antiknock performance data obtained in the present investigation resulted from engine studies made with 27 aromatic hydrocarbons in blends with selected base fuels. On the basis of these data, the relations between molecular structure and antiknock value and the influence of engine operating conditions on these relations for the aromatics can be readily seen.

The relation between structure and antiknock performance for a series of *n*-alkylbenzenes at a lean fuel-air ratio

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

is shown in figure V-3 (a). In this figure it was necessary to use performance numbers for the A. S. T. M. Aviation engine, inasmuch as knock-limited indicated mean effective pressures are not measured on this engine. The first three carbon atoms added to the side chains of the aromatic compounds successively increased the blend knock limits. The addition of a fourth carbon atom to the side chain caused a sharp drop in performance at the full-scale single-cylinder cruise condition and a slight drop in the A. S. T. M. Aviation engine.

More specifically, the data in figure V-3 (a) indicate that, for the full-scale single-cylinder cruise condition, the 25-percent benzene blend has a knock limit 20 percent higher than the base fuel; toluene is 28 percent higher; ethylbenzene, 35 percent higher; *n*-propylbenzene, 47 percent higher; whereas, *n*-butylbenzene is only 11 percent better than the base fuel. At the other experimental conditions (fig. V-3 (a)), the trends are the same but the magnitude of the increases is less. In fact, under simulated full-scale take-off conditions the benzene blend is lower in performance than the base fuel, which is represented by the ratio 1.0. In the A. S. T. M. Aviation engine, the base fuel has a performance number of 120 and, with the exception of *n*-propylbenzene, all the aromatic blends have performance numbers lower than 120. This depreciation in performance is characteristic of aromatics at conditions as severe as those encountered in the A. S. T. M. Aviation engine.

Figure V-3 (b) is similar to figure V-3 (a) except that the fuel-air ratio is rich and the A. S. T. M. Supercharge (rich) rating method has replaced the A. S. T. M. Aviation (lean) rating method. The trends shown are somewhat different from those in figure V-3 (a), but the similarity between the A. S. T. M. Supercharge data and the full-scale data is apparent. At the conditions investigated, the first addition

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

of a carbon atom to the benzene ring produces a sharp improvement in performance; the next addition results in a decrease except for the A. S. T. M. Supercharge data, which are unchanged; the next addition slightly increases the performance; and the addition of the fourth carbon atom to the side chain results in a very sharp decrease in knock limit, as found at the lean conditions (fig. V-3 (a)).

The change in performance accompanying changes in molecular weight in an homologous series is illustrated in figures V-3 (a) and V-3 (b). The effect of different isomeric structures on performance when the molecular weight is unchanged is shown in figure V-3 (c). For this example, the four butylbenzenes, *n*-butylbenzene, isobutylbenzene, *sec*-butylbenzene, and *tert*-butylbenzene, were chosen. At the two 17.6 engine conditions and the A. S. T. M. Aviation condition, changing from the normal to the iso, the secondary, and the tertiary structures progressively improves the performance. Under simulated full-scale cruise conditions, the isobutylbenzene is slightly better than the *sec*-butylbenzene, but the small difference in antiknock value is probably insignificant.

Data for the four butylbenzenes at a rich fuel-air ratio are

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

presented in figure V-3 (d). The trends shown in this figure are similar to those found in figure V-3 (c).

Generally speaking, in figures V-3 (a) to V-3 (d), the trends in performance of the aromatic blends in the standard A. S. T. M. Aviation and A. S. T. M. Supercharge engines were similar to those in the other engines. This similarity among engines, however, is not always observed over wide ranges of operating conditions. Nevertheless, the comparison of performance characteristics of the organic compounds throughout the remainder of this chapter will be based primarily upon the A. S. T. M. Aviation and A. S. T. M. Supercharge engine data because these data were obtained in engines currently accepted as standards for rating fuels.

The knock-limited performance of dimethylbenzenes (xylenes) is illustrated in figure V-3 (e). In both engines, the 1,3-dimethylbenzene blend gave higher performance than either 1,2- or 1,4-dimethylbenzene. The 1,4-dimethylbenzene has an antiknock rating only slightly less than that of 1,3-dimethylbenzene but still considerably higher than that of 1,2-dimethylbenzene.

The trends shown in figure V-3 (f) for the methylethylbenzenes are the same as those shown in figure V-3 (e) for the dimethylbenzenes; that is, 1-methyl-3-ethylbenzene is appreciably better than 1-methyl-2-ethylbenzene and slightly better than the 1-methyl-4-ethylbenzene. A similar result was obtained for the diethylbenzenes (fig. V-3 (g)).

The antiknock performance of disubstituted compounds is illustrated in figures V-3 (e) to V-3 (g). Figure V-3 (h) illustrates antiknock trends for trisubstituted compounds.

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

The 1,2,4-trimethylbenzene blend has a slightly higher knock limit than the 1,2,3-trimethylbenzene blend in the A. S. T. M. Supercharge engine but has a slightly lower knock limit in the A. S. T. M. Aviation engine. The 1,3,5-trimethylbenzene is considerably better than either of the other trimethylbenzenes.

The relative antiknock characteristics of all the aromatic hydrocarbons examined are presented in figure V-3 (i) at

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

A. S. T. M. Aviation lean conditions. About 15 aromatics improved the knock-limited performance of the base fuel. These particular blends fall within a range about seven performance numbers above the base fuel. From these data at lean conditions, 1,3,5-trimethylbenzene and *tert*-butylbenzene appear to be the most desirable aromatics in the 25-percent blends investigated.

(i) Aromatics; lean conditions.

FIGURE V-3.—Continued. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

The aromatic blends are compared at A. S. T. M. Supercharge rich conditions in figure V-3 (j). In contrast to the A. S. T. M. Aviation data (fig. V-3 (i)), the 25-percent addi-

tions of aromatics to the base fuel caused considerable improvement in A. S. T. M. Supercharge performance, from a performance number of 112 for the base fuel to about 176

(j) Aromatics; rich conditions.

FIGURE V-3.—Concluded. Knock-limited performance of aromatics in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-4.—Knock-limited performance of ethers in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-4.—Continued. Knock-limited performance of ethers in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

for the best aromatic. These results are consistent with results obtained by other investigators in that aromatics in fuel blends generally offer considerable advantage at rich fuel-air ratios but only moderate improvement or even depreciation at lean fuel-air ratios under severe operating conditions. The 1,3,5-trimethylbenzene and *tert*-butylbenzene blends, which have good antiknock characteristics at A. S. T. M.

FIGURE V-4.—Continued. Knock-limited performance of ethers in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-4.—Continued. Knock-limited performance of ethers in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

Aviation conditions (fig. V-3 (i)), were still relatively high in performance at rich conditions (fig. V-3 (j)) but were exceeded by other aromatics. Among these high-performance aromatics were 1,3-dimethyl-5-ethylbenzene, 1-methyl-3,5-diethylbenzene, 1-methyl-4-*tert*-butylbenzene, and 1,3,5-triethylbenzene.

In the aromatic data just discussed, only one trend appears worthy of mention, namely, that meta structural arrangements are equal to or slightly better than para arrangements in antiknock performance and both arrangements are considerably better than the ortho structural arrangement. In one case (fig. V-3 (j)), however, the para arrangement was better than the meta arrangement as shown by comparison of 1-methyl-3-*tert*-butylbenzene and 1-methyl-4-*tert*-butylbenzene. Essentially the same trend

(e) Methallyl ethers.

FIGURE V-4.—Concluded. Knock-limited performance of ethers in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

is reported in reference 1 for the relation among ortho, meta, and para compounds.

For the paraffins (fig. V-1), increasing the length of the primary carbon chain resulted in a decrease in the antiknock performance; however, for the aromatics (fig. V-3 (a) and V-3 (b)), an increase in length of a carbon side chain is beneficial up to a certain point, but further additions to the side chain are detrimental to the antiknock performance.

Ethers.—The antiknock characteristics of three alkyl ethers are illustrated in figures V-4 (a) and V-4 (b) for lean and rich fuel-air ratios, respectively. At lean conditions (fig. V-4 (a)) in the A. S. T. M. Aviation engine, isopropyl *tert*-butyl ether was appreciably higher in antiknock value than either methyl or ethyl *tert*-butyl ether. Ethyl *tert*-butyl ether appears to be slightly higher than methyl *tert*-butyl ether in this engine. In the 17.6 engine (fig. V-4 (a)) at both conditions, the results obtained for the three alkyl ethers were directly opposite to those found in the A. S. T. M. Aviation engine. Methyl *tert*-butyl ether was equal to or better than ethyl *tert*-butyl ether and both were appreciably better than isopropyl *tert*-butyl ether. This trend was found also at the rich conditions shown in figure V-4 (b).

The antiknock characteristics of five phenyl alkyl ethers are shown in figure V-4 (c). In both engines methyl phenyl ether and *tert*-butyl phenyl ether gave the lowest performance numbers. The remaining three ethers were about equal in performance in both engines. A comparison of figures V-4 (a) and V-4 (c) shows that the phenyl alkyl ethers investigated have considerably poorer antiknock characteristics than do the *tert*-butyl alkyl ethers at A. S. T. M. Aviation conditions.
